Now, all this work cannot be carried on without money. Many millions are contributed yearly by the people of Britain for the missionary cause, and as Christianity spreads in heathen lands yet more will be required. The immense sums of money we contribute are greatly to the credit of the people of this country, and more will no doubt be forthcoming as it is required. The moneys we contribute are paid into the exchequer of the several missionary organisations, and to them we look to see that this money is rightly spent. Let me say at once that the missionary societies which send out their missionaries without granting them the opportunities of—nay, insisting upon—learning something of medicine; surgery and hygiene are not fulfilling their trust. They are juggling with the lives of men and women in a manner which, did the people in this country appreciate it, would lead many charitable persons to close their purses with a snap, and to say, "I will contribute no more until you mend your ways." I should like my words to reach the ears of all the authorities of these societies, as well as those of the public who contribute the money. It is difficult to do that, however, by speaking or writing mere platitudes; it will require a "scene" of some kind before the public can be aroused to the situation; it would require someone in church, when on the next occasion money is being asked for missionary societies, to stand up before the collection is made, and to say, "Sir, are the missionaries you intend to send out, with the money we are willing to contribute, to be properly equipped for their work by being trained in elementary medicine and surgery? because if not we will take no part in encouraging these estimable men and women to go to their death." Could someone be found to have the courage to do this the matter would be settled for ever; no money would be forthcoming to societies who betrayed the confidence the public place in their work and methods. Surely this very humane work can be done without some such vulgar appeal to unruly sentiment. Surely it is not necessary to have scenes in church to rouse the public conscience in regard to the lives of missionaries. The missionary societies are not so numerous but that they cannot be appealed to individually; and, although we are told a committee has no conscience, the men on these committees are sensible Christian men, and the fact that they are dealing with the lives of men and women must surely come home to them.

Livingstone College the European Centre for Training Missionaries in Elementary Medicine.

I have spoken strongly on this subject because I feel strongly; and had I more power to deal with the matter I should not rest until I had made it compulsory by law that no missionary leaves these shores for work in the tropics until he can satisfy the charitable public that he is properly equipped for the task. The lives of the missionaries are as much a national asset as the lives of the men who go into the public services or join commercial firms; and just as government servants and merchants are necessary for our imperial wants, so are missionaries necessary to fulfil the desires of the people of this country that religious teaching shall be given to the heathen!

Attempts at teaching some elements of hygiene are made elsewhere than at Livingstone College, but at this college alone is a systematic course given which is calculated in any way to meet the objects in view. As usual, we are slow in this country to entertain or to act upon a new idea; not so some of our Continental neighbours, and several of the western European nations send their missionaries to be trained at Livingstone College.

Do not be Impatient when the Natives Hesitate to Ask your Advice.

I would like to give a word of warning to young missionaries. Do not be disappointed if you find the natives inclined to "stand off" at first. You may think it ungrateful of them not to trust you at once and to be unwilling to place their lives in your hands. Here in England we do the same thing, we stand off a bit, to see what the new doctor is like, and so you cannot blame these people if they do not throw themselves at once into a recently-arrived doctor's hands. But when you gain their confidence the "medicine" man is to the natives supreme. I remember in Egypt during the cholera expedition of 1883, when I happened to be one of the men who volunteered for service, I went to a village where I was told there were numbers of people dying, but I could find no cases. I searched about for two or three days, but could not find any evidence of cholera, and I telegraphed to the authorities in Cairo "I am sorry"—I should have said, I suppose, I was glad—"I am sorry, but there are no cholera cases here." At last one of the Egyptian soldiers who accompanied me in my rounds began to trust me, and he took me to a house where he knew there was a case of cholera. I went with him to the door, and there was the mother of the lad who was said to be ill with cholera, standing at the door, and declaring there was no case of cholera in the house. We pushed past her, and we searched everywhere for that patient. It was not a large house, we soon went all over it, but there was no sign of a patient. At last under some hay in front of the buffalo I saw something move, and gathering up the hay I found the sick lad. The patient recovered, and then I began to get cholera patients in scores. Within twenty-four hours I had 200 patients. The people thought that the British Government intended to punish them; we had been at war with them in 1882, and they thought we were sent out in 1883 to complete the destruction of the country and the people. That was the light in which the doctors were looked upon, and one can scarcely wonder at the backwardness of the people to accept our services.

Again, do not be too ready to come to the conclusion that there is no such thing as some particular disease in a district because you have not seen it. You may say to yourself:—"I cannot find any of these diseases I was taught so much about at Livingstone

isolated by other workers. Detailed bacteriological work and experiments proved, however, that such micro-organisms have nothing to do with the production of the disease, and in the light of our present micro-biological knowledge must be regarded as extraneous organisms isolated and fully described by investigators using somewhat defective technique. The bacteriological examination of Wright's so-called primary lesion, *i.e.*, damaged gastro-duodenal mucosa resulted in the isolation of many rod-shaped bacteria, the biology of which showed them to be nothing more or less than ordinary intestinal micro-organisms. In summing up our bacteriological results, our investigations strongly point to the conclusion that *beri-beri is not due to any micro-organism of the hitherto described types.* Indeed *we doubt if the disease is an acute specific infectious disorder.* So far our results are against its being so.

Animals not liable to the disease.—Coming to the experimental part of the report, the results of our attempts to induce the disease in any of the common domestic animals are decidedly a failure. In no single instance, out of over fifty miscellaneous experiments upon monkeys, pigs, calves, sheep, fowls, rabbits, &c., were we able to call forth even the shadow of a symtom or sign of beri-beri.

Comparing the results of these experiments with the series carried out by Durham, who also had negative results, it would appear that it is impossible to convey beri-beri directly from man to animals. So far as published records are concerned, monkeys are the only animals which appear to have contracted the disease, and then only under natural conditions. These—the experiments of Hamilton Wright and published in a recent number of "Brain"—however, are isolated observations, and judging from the recent remarks of Durham in the *Journal of Hygiene* some doubt would appear to exist as to the real condition of the monkeys described by Wright as suffering from beri-beri.

The question as to whether any animal can contract beri-beri direct from man, or indirectly through some other channel, must remain open. Our own opinion is decidedly against the conveyance from man to animals. With the exception of Hamilton Wright's experiments, which must be received with due caution, *there are no reliable records of beri-beri in animals.* Indeed it would be difficult to experiment along these lines with hope of success in the absence of the etiological factor and its point of invasion of the body.

Our experimental researches bring us further along the line of our conclusions as to the non-micro-organismal nature of beri-beri. Up to the present time none of our researches have guided us to form a conclusion that it is a specific infectious disease. Indeed all the evidence contained in this report is against such a conclusion.

The premises upon which we built up such a statement so antagonistic to the theories of Hamilton Wright are the following:—

(*a*) There is no evidence of a primary lesion, *i.e.*, a point of invasion of the virus into the body. This, however, carries with it very little weight, as many specific infectious diseases have a somewhat cryptogenous point of entry into the human tissues.

(*b*) No specific micro-organisms can be found in any organ or tissue of any case of beri-beri which can be brought into close causal relationship with the disease. The micro-organisms found in Wright's so-called primary gastro-duodenitis are to be regarded as ordinary bacteria belonging to the intestinal flora.

(*c*) Experimental researches are negative. The blood contains no organisms, and the transference of large quantities of beri-beri blood to the tissues of healthy animals never induces disease.

Similar results are obtainable with the spleen, liver, brain, &c.

When we come to the gastro duodenal mucosa as found in acute and rapidly fatal cases of beri-beri, and use an emulsion of this for feeding monkeys—animals said by Wright to contract beri-beri naturally—and obtain uniformly negative results, our faith becomes somewhat shaken in the micro-organismal nature or the specific infectivity of beri-beri.

In conclusion, the results of our researches are directly opposed to those of Hamilton Wright, and in more or less harmony with those of Durham.

Of late years a considerable diversity of opinion would appear to prevail as to the isolation of beriberics and the treatment of beri-beri cadavers. From our researches we can see no valid reason to suppose that in beri-beri we are dealing with a highly infectious disease. Indeed beyond the removal of such patients to surroundings light and airy, with the regulation of a liberal and wholesale diet, nothing more would be required to add to the sum total of the necessary sanitation.

As regards the burial of beri-berics, this, in our opinion, is of no vast importance apart from the question of the decomposition of the body. If provision during burial is made for rapid decomposition, as now laid down by all hygienists, no danger will accrue.

Having summed up the results of our investigations into this interesting disease it but remains to speculate on a theory as to its etiology. In these days everyone strives to have a theory in regard to the etiology of a disease like beri-beri. Whether such a course is advisable, in the absence of any definite data, we leave open for speculation.

Reviews.

MEDITERRANEAN FEVER IN INDIA: "Scientific Memoirs." By Officers of the Medical and Sanitary Departments of the Government of India. "Mediterranean Fever in India: Isolation of the Micrococcus Melitensis," By Captain George Lamb, M.D., I.M.S., and Assistant-Surgeon M. Kesava Pai, M.B., C.M. (Madras). New Series. No. 22. Price 10 annas, or 1s.

Captain Lamb and Assistant-Surgeon Pai have succeeded in establishing the fact that Mediterranean fever is met with amongst residents or natives of India. In eleven of the cases the *M. melitensis* was isolated from the spleen during life. Nine of the patients were Sepoys of the 27th Punjabis, Multan; one was a Sepoy of the 12th Sikhs, Ferozepore; and

Back Row: A. Reid (Junior House Surgeon), W. Smith Allan, A. Ingram, H. L. Deck, Mr. H. C. Staniland Smith, A. B. Tighe, Capt. E. L. Perry, I.M.S., E. Robledo, G. B. Warren (Laboratory Assistant), L. A Prins, B. M. Flood.

3rd Row: Dr. C. W. Daniels (Medical Superintendent), J. Ottley (Staff Surgeon, R.N.), A. E. Ridsdale, W. M. Wade, Capt. L. P. Stephen, I.M.S., Capt. F. N. White, I.M.S., J. J. Zellweger, J. McW. Bourke, J. P. Ziervogel, Capt. A. W. Cook Young, I.M.S., B. M. McVail (Senior House Surgeon), Capt. L. L. G. Thorpe, R.A.M.C., R. T. Booth, J. Cross, G. Portioli-Rocca.

2nd Row: A. T. Stanton (Demonstrator), Dr. F. E. Fremantle (Lecturer), Dr. B. S. Postwalla, Miss Dinbai Furdoonji Petit, Mr. Jehanjir Bomanjee Petit, Mrs. Manekbai Bomanjee Petit, Sir Patrick Manson, K.C.M.G. (Lecturer), Mrs. Goolbai Bomanjee Petit, Sir Francis Lovell, C.M.G. (Dean), The Hon. Bomanjee Dinshaw Petit, Dr. F. M. Sandwith (Lecturer), Mr. P. Michelli (Secretary), Miss K. Wyss, Miss L. G. Thacker.

Front Row: Major E. Wilkinson, I.M.S., H. W. Kirby, H. P. Kennard, E. N. Graham.

LONDON SCHOOL OF TROPICAL MEDICINE.

21st Session. May-July, 1906.

Bale and Danielsson, Ltd., London.

one was a man, also from Ferozepore, ten years resident in India.

In six of the cases no splenic puncture was made, the diagnosis resting solely on the clinical history and the serum agglutination reaction. Two of the cases were Sepoys in the 27th Punjabis, Multan; one was a prisoner in the Ferozepore jail; two, a man and a woman, resident in Lahore; one a native of Murree. There was found to be a great difference in the agglutination value of the sera in the different cases. The *M. melitensis* was isolated from the spleen at various stages of the disease, in most instances whilst the temperature was still high and the illness more or less acute.

Although many of the cases occurred in the same regiment, careful investigation failed to bring forth any evidence in support of common infection. The men belonged to different companies, to different races, slept in different barracks, and practically never met. The 27th Punjabis, in which regiment the majority of cases of Mediterranean fever occurred, were stationed at Multan since January 29th, 1905; previously the regiment were quartered at Ferozepore, also in the Punjab, and many cases of a kind resembling Mediterranean fever had occurred in the regiment before leaving Ferozepore for Multan. The 15th Sikhs succeeded the 27th Punjabis at Ferozepore, and one man of the former regiment developed Mediterranean fever at Ferozepore. This, however, seems to have been the only case, so that the infection left behind by the 27th Punjabis cannot have been severe. The explanation of the 15th Sikhs escaping the disease so markedly is believed to be due to the fact that over two months elapsed between the arrival of one regiment and the departure of the other.

A Vocabulary of Malay Medical Terms. By P. N. Gerrard, B A., B.Ch., M.D. (Dublin). D.T.M.H. Cambridge. Singapore: Kelly and Walsh, 1905. Pp. 107.

This useful book is well adapted for the purpose for which it was written. In addition to the vocabulary one finds valuable information in the preface. In the appendix will be found sentences for conversational purposes applicable to obtaining the clinical histories of such ailments as beri-beri, venereal diseases, fevers, cases of consumption and of dysentery. Snellen's Vision Test types, adapted to Malay requirements, form a useful practical addition to the vocabulary.

Correspondence.

To the Editors of the Journal of Tropical Medicine.

Sirs,—In Lieut.-Colonel Giles' article on "Biting Flies," in your issue of April 2nd, he quotes the old French saying "les mouches d'automne pignoient" as probably referring to members of the genus *Stomoxys*, and not to the common house-fly. Under certain weather conditions, however, I have on several occasions—both in South Australia and in Scotland—experienced a slight but irritating "bite" from the latter. The climatic conditions under which this happens are dull autumn days, when summer is just passing into winter and the housewife is in doubt about laying fires. The species is unquestionably the common house-fly, but how it produces the faint sting I cannot say. Surely it is this occasional occurrence to which the French refer.

Yours, &c.,

Perth, W. Australia. J. Burton Cleland.
June 9th, 1906.

With reference to the above it may be remarked that although the ordinary method of taking food, in the house-fly and its allies, is by means of a sort of licking action performed by the lobes of its so called "tongue"; these insects are nevertheless provided with a short pointed labrum and a hypopharynx hidden above the roots of the former. Though hardly suited for actual piercing, these would be quite capable of giving the slight prick occasionally inflicted by the common fly, which, however, probably only does so accidentally in its effort to obtain as much as possible of the perspiration of the person on which it has settled. Admitting this, however, I believe that *Stomoxys* is far more commonly the real culprit.

Personal Notes.

Indian Medical Service.

India Office: Arrivals of Indian Medical Officers in London.—Captain R. E. Lloyd, Captain R. M. Dalziell, Captain R. M. Carter, Major J. B. Smith.

Extensions of Leave.—Lieutenant-Colonel W. S. Eyres, 6 m. Med. Cert.; Captain R. M. Dalziell, 3 m., Med. Cert.

Permitted to Return to Duty.—Captain E. C. Maddoch, Major J. K. Close, Lieutenant R. F. Steel.

Postings.

Captain A. G. Sargent and Captain W. H. Cagaly, services lent to Government of Bombay.

Major Grayfoot, to be Med. Officer, Sind Rifles.

Colonel Benson officiates as Surgeon-General, Madras, with temporary rank.

Major Anderson, Civil Surgeon, Tippera.

Assistant-Surgeon Daley acts as Civil Surgeon, Balasore.

Lieutenant-Colonel G. H. Bull officiates as P.M.O., Bombay.

Major E. R. Parry acts in additional charge as Civil Surgeon, Dacca.

Captain Mathew, services lent to Government of Burmah.

Major A. R. S. Anderson, services placed at disposal of Government, East Bengal and Assam.

Lieutenant-Colonel Dennys officiates as Agency Surgeon and Admin. M. O., N.W. Frontier Province.

Captain Flening, I.M.S., Civil Surgeon, Peshawar.

Major Bidie, Captain Feslir, and Captain O'Neill, services placed at disposal of Government of Madras.

Colonel D. ffrench Mullen, services temporarily placed at disposal of Commander-in-Chief.

Leave.

Major P. P. Kilkelly, Privilege and Study, 1 y.

Lieutenant-Colonel R. N. Campbell, privilege leave, 2 m. 28 d.

Mr. Gibson, Assistant Director, Plague Research Laboratory, Bombay; leave, 2 y.

Captain N. Collinson, leave on Med. Cert., in anticipation of formal sanction.

Dr. P. A. Rigby, Civil Surgeon, Balasore, combined leave, 6 m.

Notes and News.

Punjab Medical College Affair.—Over a hundred students of the medical school at Lahore, who were out "on strike," have come in and made submission. About 164 others, including the ringleaders, still stand out.—*Pioneer Mail*, June 15th.

Recent and Current Literature.

A tabulated list of recent publications and articles bearing on tropical diseases is given below. To readers interested in any branch of tropical literature mentioned in these lists the Editors of the JOURNAL OF TROPICAL MEDICINE *will be pleased, when possible, to send, on application, the medical journals in which the articles appear.*

"Bulletin de L'Institut Pasteur," June 15, 1906.

"The Serotherapeutics of Plague" (La Sérothérapic de la Peste), by Dr. Edward Dujardin-Beaumetz.

As soon as ever Yersin discovered the pathogenic agent of bubonic plague in the epidemic which was raging in Hongkong in 1894, he sent specimens of this microbe to the Pasteur Institute, where Roux and his colleagues, Calmette and Borel, made vaccination experiments. By using cultures killed by heating to a temperature of 60° C., they succeeded in vaccinating animals, and proved that their serum possessed preventive and curative properties in experimental plague infection, since when horses have been immunised to supply the necessary serum for the treatment of human plague. The process consists in intravenous injections into the jugular veins of the horses, first of emulsions of microbes killed by heat, and afterwards of living microbes which have been rendered hypervirulent by passage through guinea-pigs and rats. The process is a somewhat lengthy one, as it takes from five to six months, for the vaccinations have to be repeated weekly and in progressive doses before an antitoxic and antimicrobic serum can be obtained which—after due experiments on animals—can be used for human serotherapeusis.

The test used at the Pasteur Institute for the dosing of the anti-plague serum consists in inoculating a mouse with plague, and sixteen hours later injecting it with $\frac{1}{10}$th of a cubic centimetre of serum. The recovery of the mouse testifies to the sufficiency of the activity of the serum. In man, the efficacy of an anti-plague serum as a preventive measure has been fully proved, but the effect is only a transient one, and passes away after a period of about ten days, so that a fresh injection of the serum is then again necessary to keep up immunity. If the focus of the epidemic is a restricted one, these injections are of great service; but serotherapeusis as a preventive measure is out of the question in a country where plague is endemic. In this latter case recourse must be had to the injections of microbic emulsion killed by heat, after the method recommended by Haffkine. In this case immunity is acquired more slowly, but, on the other hand, it lasts longer, and may even persist for several months.

A lengthy list of the world-wide series of vaccinations undertaken up to date is now given, with their several results, and with their varying success. The difference is accounted for as follows:—The anti-plague serum was given too late; in insufficient doses; only rarely by the intravenous method; and lastly, the serotherapeutic treatment was suddenly stopped as soon as the high temperature fell.

As far back as 1898, Simond noticed that among the Hindoos treated, those who received the serum on the first day of the disease had a mortality of 20 per cent. only, those treated on the third day 36 per cent., on the fourth day 66 per cent., and lastly, on the fifth day, 100 per cent. of deaths.

If, therefore, early intervention in the treatment of plague has a favourable influence on the prognosis of the disease, the quantity and the method of the administration of the serum are also no less important. The doses of serum in plague must necessarily be much higher than those used in general practice, as, for instance, in diphtheria, where there is a well-defined lesion only to deal with; in plague, on the contrary, the glandular affection may be general from the beginning, and the plague germs may be present in the circulation of the blood.

In order to successfully counteract such a severe onset, it is necessary to inject large and repeated doses of the serum. Duprat, at Rio-Grande do Sul, administered *subcutaneously* doses of 200 to 300 cc., and even more, as a first injection, and, according to the severity of the disease, injections of 100 to 150 cc. were repeated every twelve hours. This method gave only a mortality of 15 *per cent.* Apart from other objections, this method, however, requires one to have enormous quantities of serum at one's disposal, which is not always feasible during an epidemic.

Now the *intravenous* method allows of the organism becoming saturated immediately with antitoxin and in lesser doses. Calmette and Salimbeni, at the time of the epidemic in Oporto, showed the efficacy of this method by obtaining unhoped for cures in severe cases, and especially in pneumonic plague. The quantity injected at any one time, then, never exceeded 40 to 60 cc. of serum.

Since then Penna, of Buenos Ayres, has systematically used the intravenous method for treating his cases in the isolation hospital. He first injects not less than 100 cc., followed by a similar injection twenty-four hours later, and, if there is then no perceptible improvement, by a third injection. His death-rate does not exceed 14·2 *per cent.*

The serum has also been administered through the peritoneal cavity, with a mortality of 18 per cent.; but this method is not strongly recommended even by its authors.

The following is briefly the procedure for intravenous injection: The veins selected are those on the back of the hand or on the front of the wrist, or in dark-skinned races on the anterior surface of the fore-arm. The serum must be thoroughly limpid and slightly warmed; the needle is plunged into the vein, and the syringe (filled with the serum and with every air-bubble carefully removed) is then adapted to it; the injection is then very slowly forced on; a drop of collodion over the small needle wound is the only dressing required. There is generally great reaction after an intravenous injection, but the symptoms afterwards improve suddenly, almost as if by crisis; the intense glandular pains cease, and in twenty-four hours plague germs have disappeared from the peripheral circulation, and an examination of the glandular juice shows the absorption of the cocco-bacilli by the polynuclear leucocytes. The accidents due to the serum, such as œdema, erythema, or arthralgia, are only such as sometimes happen with ordinary therapeutic sera, and bear no relation to the doses of the injections or to the methods of introducing the same, and are merely due to the toxic properties normally found in horse blood-serum.

Lastly, the use of *large doses* of anti-plague serum and their administration by *intravenous* injection, cannot be too strongly insisted upon, as serotherapeusis has hitherto proved the only really efficacious treatment of plague, which still claims too many victims.—(J. E. N.)

STUDIES IN PLAGUE.

By Professor Dr. CAMILLO TERNI.

Biological Laboratory, Museum of Natural History, Milan (Italy).

THOUGH the researches of Kitasato [1], Yersin [2], and of the different scientific commissions in India have solved the problem of the etiology and pathology of plague, we have advanced very little in our knowledge of the treatment of the disease. We have regarded plague exclusively as a septicæmic infection of so rapid a course as to confound the local with the general manifestations. All the specific treatment has therefore been exclusively based on serum therapy, regarding it of value even though all evidence points to the absence of success by this mode of treatment.

The laudable desire to obtain for plague the success which till now serum therapy has given only for diphtheria must not delude us into the belief that there are no other means of treatment.

Therefore, after these years of trial during which anti-plague serum has had a large and well-nigh exclusive application in the treatment of plague, it seems to me useful to state some observations made by myself in numerous clinical cases treated by different methods.

PART I.

THE EFFICACY OF PLAGUE SERA.

In a preceding study [3] I had occasion to point out that the plague bacillus in man does not wholly behave as a septicæmic bacterium comparable to anthrax, and that the penetration of, and the diffusion in, the organism does not happen directly by way of the blood. All the clinical and experimental facts show that plague in the beginning is limited to the lymph system, and especially to the glands, where the plague bacillus finds the most favourable conditions of life and development, producing in the so-called bubo a process of inflammation and necrosis, and the formation of extremely toxic substances which, absorbed, give rise to the gravest and most characteristic symptoms of this infection. The presence of the bacilli in the blood always happens at a very late period, and is a secondary factor in the course of the disease; whilst death usually occurs even before the bacilli from the lymphatics appear in the blood in consequence of the grave intoxication of the products elaborated in the bubo acting with a paralysing effect on the capillary circulation. In many cases also after the blood is infected, we may still obtain spontaneous recovery when the general intoxication is less grave [4]. In plague, therefore, the greatest danger to the patient's life depends on the quantity of toxins elaborated by the bacilli in the predilected focus of the lymphatic system, or in tissues of selection, as, for instance, happens in cases of primary plague pneumonia, in which sudden death by capillary vaso-motor and cardiac paralysis is the ordinary issue, whilst the local lesions are of little consequence in determining a fatal issue (Lutz [5], W. C. Hossack [6], L. F. Childe [7]).

In these conditions it is natural that to obtain a specific treatment of plague, the first requisite of the serum must be a remarkable anti-toxic power, especially in the grave cases, when the inflammation at the point where the bacilli are concentrated has reached the necrotic phase, so that phagocytic action is almost in abeyance owing to the impenetrability of the dead tissues, and toxins are thus allowed to run riot, with grave danger to the patient's life.

The essential conditions of the pathologic process of plague, which I was the first to state, have been amply confirmed by the English Commission in India [8], who opportunely observe that in plague there takes place a combined process of invasion and intoxication, and that therefore it is evident that two different qualities of the therapeutic substances must possibly be applied in the treatment of plague. In the first place, anti-bacterial substances capable of killing or checking the growth of the bacteria; in the second place, anti-toxic substances must be applied in order to eliminate or alleviate the symptoms produced by the bacterial poisons, by which is especially compromised the natural resistance of the organism against infection.

Do the curative anti-plague sera actually in use correspond to the fundamental therapeutic conditions above stated? Certainly not. Yersin's first experiments were too hasty, as proved by their want of success during an extended trial, and they wanted the precision attending the process of animal immunisation according to Calmette's and Borrel's and later Roux's [9] proposals (entire and virulent cultures inoculated into horses in gradually progressive quantities).

Yersin's preparation. The principal fact which characterises the plague infection is that the complexity of the symptoms of intoxication appears as soon as the bacillus instals itself in the lymphatic glands and sets up a bubo. Every observer who has studied the serum therapeutics of plague must now be persuaded that no animal, ordinarily at disposal for such preparation, produces an anti-toxic serum in the highest degree suitable for the treatment of plague; and that it is not even possible to obtain a high anti-bacterial power, to give sure and constant results in the initial period of the infection, when the symptoms of intoxication are not yet manifest.

With the method proposed by Lustig [10] it seemed theoretically easier to obtain the vaccine with a greater degree of solubility, and presumably more assimilable, from the chemical treatment it underwent in the preparation; but we are again confronted with another error, because it is demonstrated that the horses destroy only to a small extent the plague nucleoproteid, and that they do not produce in their serum efficient curative substances. From this point of view it is therefore still better to follow the method of inoculating entire and virulent cultures, by which we obtain a greater stimulating action on the phagocytes and the production of anti-bacterial substances which, though feeble, are yet active enough in the fresh serum, especially if we use for the preparation mules, asses and oxen instead of horses. By using horses we are apt to find that the serum has a toxic action instead of a curative one, on account of the undestroyed bacterial poisons which continue to be still active in the serum.

This perhaps explains the fact that in India the mortality was greatest among those treated with serum, although the "cure" began on the first day of the illness, when the conditions are most favourable for obtaining good results.

The English Commission after years of observations and experiments came to the following conclusions on the question of the anti-plague sera :—

(1) "Though the method of serum therapy as applied to the plague has not yet been crowned with a therapeutic success in any way comparable to that obtained in the treatment of diphtheria, none the less the method of serum therapy is in plague, as in other infectious diseases, the only method which holds forth a prospect of ultimate success.

(2) "The serum treatment has not as yet been sufficiently successful to make it desirable to extend the treatment, under present conditions, as a general measure over all the districts affected with plague. Rather, it appears to us that the imperfections of the present methods of preparation and application should be fully recognised, and that it should be realised that the line of progress lies, not in the direction of applying the sera at present available to the largest number of patients, but in the direction of studying in the case of the animals who furnish the serum the blood changes which are associated with the incorporation of the plague toxins, and with the elaboration of antidotal and bactericidal substance. In like manner, we think that the condition of the blood in the human plague patient and the changes brought about by the administration of the serum should be carefully studied."

These principles we kept constantly before us when working in the laboratory of Messina at the serum therapeutics of plague.

How to prepare by various methods an anti-plague serum of high anti-toxic power was our constant endeavour, and I have already published the researches and the results, which are without doubt superior to those obtained from the sera prepared by Yersin and by Lustig Galeotti, both in the treatment of man and in the experiments on animals. The difference of method in the preparation of serum produced by Yersin and by Lustig Galeotti is not calculated to determine much difference in the quality of the products and in the curative effects; because the former inoculated into the horses either filtrates of cultures or entire cultures; the latter utilised the protein extracted chemically from the dead bodies of plague bacteria. Neither with the one nor with the other method is it possible to obtain a serum with marked anti-toxic action, especially if horses are used for the preparation, and the result of the treatment is merely a stimulus of the phagocytic action, which is not always decidedly manifest even when intravenous inoculation is employed. A slight advantage may be noted in favour of Lustig's serum, as we may infer from the statistics of the Arthur Road Hospital in Bombay, which, however, are not free from faults of method and calculation.

Similar results in treatment of plague we may obtain with the artificial sera of Hayem and of Fodor, and still better by the inoculation of corrosive sublimate proposed by Bacelli on account of the great stimulating power exercised by the sublimate on the leucocytes.

After testing by numerous experiments the toxic action of the pathogenic plague products in man and in animals in contrast with those of the artificial cultures, I proceeded to immunise the animals with the products derived from the infected organism (peritoneal exudate of plague-infected guinea-pigs, juice of buboes, &c.) instead of artificial cultures. As the horses exhibited but little resistance against the action of similar products, we substituted mules and oxen for horses, with very promising results; the anti-bacterial and anti-toxic value of the serum obtained by this method, compared with that of the serum from horses immunised with cultures or with Lustig's nucleo-proteid, stands in the proportion of 50 to 1.

The serum prepared according to this method has been amply applied in Brazil side by side with the sera of Lustig and Yersin. The results, however, though favourable to the new method, showing a total mortality of patients treated with this serum of 25 per cent. only, always leave some doubts on account of the relatively limited experience, and from the fact that epidemics often vary in intensity and virulence. Moreover, my serum was recently prepared, whilst the other two sera used were much older. The great instability of the anti-bacterial and anti-toxic substances of anti-plague serum, no matter how prepared, makes it very difficult to have accurate comparable statistics, when either the sera employed are not the same age, or when the epidemics vary in virulence.

Judging from experiments upon animals, plague often takes on a rapidly septicæmic character, showing that the anti-bacterial substances of the anti-plague serum are rapidly eliminated, so that the results vary sometimes with the same sample of serum if it is first used fresh and then after only four or five days. The same has been stated by the English Commission regarding Lustig's and Yersin's sera [11].

To this circumstance must I ascribe the unsuccessful results obtained in Bombay with my serum, which has been tried in a series of 300 patients under the direct control of Mr. Haffkine, to whom I am deeply indebted for so generously allowing so extensive a trial of my preparation. The serum could be applied only after a delay of nearly six months, and it was impossible to substitute it in time with a fresh one.

The instability of the therapeutic substances of anti-plague serum just related is, however, confirmation of the slight (if any) specific action which it possesses.

By none of the known methods have the serum therapeutics of plague been settled, and in the gravest cases the deficiency of the curative power of the serum on account of the feeble and inconstant anti-toxic action is manifest. With the animals ordinarily at disposal in the laboratories for the preparation of sera on a large scale, it is so far impossible to obtain an anti-plague serum which has a curative anti-toxic efficacy in any way comparable to that of the anti-diphtheritic serum, and to this deficiency we must ascribe the failure of serum therapeutics in plague. Only from man convalescent from grave forms of plague, or from monkeys (*Macacus rhesus*) and from rats (*Mus decumanus*) is it possible to obtain a very active anti-toxic and anti-bacterial serum (reducing to 20 to 30 ccm. of

serum the normal dose of U.I.) sufficient for the treatment of cases with the gravest broncho-pulmonary complications, which till now remain intractable to any kind of anti-plague serum. When great quantities of material are required during an epidemic, it is practically impossible to obtain sera of similar strength, owing to the demand exceeding the supply.

The problem of the specific treatment of plague remains, therefore, still in great part unsolved. The advantages actually obtained with serum therapeutics are very limited, and must be considered as a *good promise for the future*, rather than as a completed or final result.

Part II.

The Surgical Treatment of Bubonic Plague.

Whoever has had occasion to examine a plague bubo in the most critical period of the disease (third to fifth day) will be persuaded that it is impossible to hope that by serum therapeutics the necrotic mass of the lymphatic glands can be destroyed, seeing that phagocytosis cannot develop effectually in dead tissue; the plague bacilli, therefore, develop rapidly and eliminate toxins, which, in conjunction with the other soluble poisons of the bacterial bodies in disintegration, tend to infect the patient's blood and tissues.

By studying the natural evolution of the disease, one arrives at a rational method of treatment.

In the cases of spontaneous recovery the fever falls by crisis after twenty-four to forty-eight hours, and the infection stops before the real bubo is formed, limiting itself to the inflammation of one or two glands. In other cases the spontaneous recovery may occur in a more advanced period of the disease when the bubo is completely developed, that is, when the inflammation affects the majority of all the glands of a given region. In these cases the bubo begins to fluctuate after the critical period (third to fifth day), and the spontaneous issue of the pus towards the tenth to the fifteenth day follows when an incision has not been made. We must therefore consider as of benign prognosis all those cases in which the plague bacillus finds itself in the buboes associated with the pyogenic staphylococcus, *not because these act by attenuating its virulency or the toxicity of the products*, as some observers thought, but because the intervention of these bacteria in the phase of suppuration favours more rapidly the resolution of the illness with the evacuation of the focus of infection. When the pus is not eliminated in time, death will surely follow either by general infection or by slow intoxication. The benefit of the rapid evacuation of the infecting and toxic products accumulated in the bubo in consequence of the suppuration determined by the pyogenic staphylococcus is so evident that since the most remote antiquity the treatment of plague consisted in hastening the suppuration and the opening of the buboes. Recently one of the physicians of Alexandria, Egypt, thought it expedient to inoculate the pyogenic staphylococcus into the plague buboes as a means of cure when they do not manifest the tendency to suppuration [12].

The contrary occurs when the plague bacillus is associated with septicæmic bacteria (diplococcus) or with the streptococcus, because early in the disease a zone of œdematous infiltration round the glands, constituting the bubo, is manifest, involving thereby the surrounding tissues and the skin in the inflammatory process. The diffusion of the plague bacilli becomes thereby easier and more rapid, and a general infection is more certain.

The natural or clinical course, which we see the spontaneous exodus of plague follows, indicates the rational method of the treatment of the disease: namely, *either the possibility of stopping the infective process at the beginning of the infection by serum therapeutics in mild cases, or surgical intervention when the progressive development of the buboes and the gravity of the symptoms of intoxication demonstrate that the specific treatment by serum is not sufficient for recovery.*

It is wholly unscientific to regard plague as quite distinct from other pathological states with which we are familiar. In other forms — lymphangitis and lymphadenitis of a malignant character, no physician would think of applying the serum as an antidote before he intervenes surgically. The only difference is that in plague the local phenomena are less evident at the commencement of the attack and are not pronounced until after general infection has shown itself. In other forms of lymphadenitis the local conditions arrest more readily the attention of the observer, and induce surgical intervention before the symptoms of general intoxication and infection are manifest.

Experience gained in the treatment of plague, especially at the Seaman's Hospital of Rio de Janeiro, allows me to affirm without hesitation that the great mortality observed in the plague hospitals results from the want of or delay of surgical intervention, because the infection remains, for a period of three to five days or more, concentrated in primary buboes and adjacent to lymphatic paths. This danger can be got rid of by eradicating the infected part, when the treatment by serum is evidently inefficacious.

From the results of numerous microscopic and bacteriologic researches made in conjunction with Drs. Gomes and Guimares, in order to determine the method of diffusion of the bacilli from the point of penetration to the bubo, I was persuaded of the benefit of immediate surgical intervention in the treatment of plague by a radical operation—the extirpation of the bubo.

In eighty-two patients who presented phlyctenules or furuncles or other primitive cutaneous lesions, it was not possible to find bacilli in the lymph extracted along the course of the lymphatic vessels between the primary lesion and the initial bubo; nor were bacilli found in the tissues surrounding the capsule of the glands.

From this fact we must infer that the plague bacillus does not find favourable conditions of development in the lymphatic vessels, and that only in the glands is to be found the true focus of infection. The diffusion of the bacilli proceeds gradually from gland to gland, and successively into all the glands of a region before it passes into another group; and the process of infection always moves in the direction of the lymph stream from the more superficial to the deeper parts, and never by the way of the blood, or by inflammation of the intermediate lymphatics, unless there are associated with the plague bacillus other bacteria (diplococcus, streptococcus), in which case

more or less diffused lymphangitis, phlebitis and œdema may be observed.

If, for instance, the primary bubo is femoral, located at the apex of Scarpa's triangle, as usually occurs, the infection extends to all the superficial inguinal glands before it reaches the deep glands situated near the crural canal; subsequently the glands of the pelvic cavity may be involved, but at the beginning of the infection, by microscopic and bacteriologic examination we may verify the infection of the inguino-crural glands, whilst the pelvic ones are still healthy. If, on the other hand, the bubo is axillary and formed by the swelling of the gland situated at the distal part of the axilla, the infection extends to all the glands of the region before it involves the subclavicular group of glands. In the cervical buboes also, if determined by primary plague amygdalitis, the infecting process limits itself for days to one or two glands of the retro-maxillar or superior cervical region without extending to the central and inferior cervical group.

In the histo-pathologic examination of the tissues, it is also easy to demonstrate that the manner of infection of the plague bacillus in the glands, as in other tissues, proceeds always by degrees in small foci, first located in the lymphatic spaces, and later becoming confluent, causing a destruction of the tissue (Albrecht and Ghon) [13], (Bandi and Stagnitta) [14], (Powel White) [15]. These pathologic localisations, characteristic of the primary bubo, distinguish it from the secondary buboes, and correspond to those of the primary foci in other organs (tonsils, lungs); they represent, therefore, the first adaptation of the virus in the new host, and are the seats where the bacilli find the best conditions to acquire the virulence and to display the successive toxic and infecting activity. Therefore we see that these primary lesions in the lymphatic channels can be more easily reproduced experimentally with cultures of attenuated virulence; whilst when the bacilli after several passages through the same animal species have obtained the greatest activity, they do not manifest themselves, because we have then an almost immediate general diffusion. Still, the evidence of their presence is at the beginning more evident in the lymphatic system, before they pass into the blood but without the evidence of localisation in initial foci.

From these observations the necessity of the immediate extirpation of the primary bubo would seem evident, and the possibility of cure, in a disease of so rapidly infecting and toxic a character as plague, will be the more certain the more we practise early elimination of the part which represents the primary localisation of the bacilli in the organism and the point of departure of the general infection. Albrecht and Ghon [16], of the Austrian Commission for the study of plague in India, came to the same conclusion, expressing the opinion that in the treatment of plague *we ought not to neglect the extirpation of the primary bubo, notwithstanding the use of the serum.*

Jamagiwa [17] has also demonstrated that the prompt extirpation of the infected glands is rational and beneficient. And Bandi [18], in some experiments made according to my advice, has also obtained good results in the same direction in animals.

In none of the more recent clinical works on plague has the empiric practice of the past been taken sufficient note of with regard to the surgical treatment of plague. From ancient times we see the principle affirmed that the recovery from plague depends on the rapid evacuation of the buboes, and in order to avoid hæmorrhage they advised the use of caustics or the actual cautery. In all the old writings on the treatment of plague the provocation of suppuration is indicated, and not to wait *too long* if this is retarded, to proceed promptly with early incision, or the use of caustics if the suppuration is not yet manifest on the second or third day.

Our first information concerning the surgical treatment of plague goes back to Hippocrates [19], to Archigenes, referred to by Galen [20], but especially to the Arabian physicians (Eba, Sina, Beitar, Isaac Iudeus, Rhazes), and was made known to Western Europe at the time of the Crusades. In the Orient to-day plague buboes are treated by native doctors by deep incisions and the application of caustics or the red-hot iron.

In the epidemics which desolated France in 1500, the surgical treatment of plague, especially by Ambrois Paré [21] and his school, was stated as the only positive and efficacious method among all the other extravagant remedies then in vogue. The same results were obtained by Settala [22] and Tadino [23] in the famous epidemics of plague in Milan in 1575 and 1630. In the epidemic of Marseilles in 1720, with the better knowledge of practice and the study of anatomy, we see introduced, besides the incision preceding suppuration and the medication with the antiseptics (detersives) of that time—salt water and vinegar, also the extirpation of the buboes by the method recommended by Manget [24].

The persistent opinion of all the ancient observers of plague that the result of the cure depends essentially on two conditions is well enunciated by Settala: *Extract in any way and as quickly as possible the matter in order that it will not spread its poison over all the body.* The necessity and efficacy of the immediate surgical intervention in plague before suppuration occurs acquires greater force by the fact that this method was advised exclusively for plague, whilst for all the other inflammatory tumours (as furuncles, anthrax and buboes of other nature) recourse was had to emollient cataplasms, that is to say, a method of expectancy or a more tardy suppuration.

As a complement of this short account of observations of the past, it is of interest to note that the French physicians, during the war for the conquest of Palestine (1799) [25], established as the general method of treatment in plague *the incision of all those buboes which did not present signs of suppuration, in order to facilitate the crisis.* Before he gave this order, Napoleon's English physician, O'Meara, had an equal number treated by incisions and by the usual method (cataplasm, emollients, or revulsives). The result was that many more recovered by the former than by the latter method of treatment.

If, therefore, so favourable and constant results were obtained in the past when the conditions were much worse and when all the technical and scientific resources of modern surgery were wanting, it seems really strange that we should still doubt the efficacy of surgical intervention in bubonic plague.

The tradition of the surgical treatment of plague continued after the above-mentioned epidemics, as we may gather from Proust [26] and Cabanes [27].

The merit, however, of drawing attention in recent years to the advantages of the surgical treatment of plague is due to J. Cantlie [28].

The extirpation of the buboes, especially when they are still in the initial period, does not present any difficulty, and is also borne by the patients without narcosis, local anæsthesia being sufficient, especially when the bubo is superficial.

The operation in the majority of cases is limited to: (1) Incision of the skin and of the superficial aponeurosis; (2) isolation of the bubo from the surrounding tissues; (3) removal of bubo; (4) examination of the lymphatic glands in the neighbourhood, especially if they are hæmorrhagic or tumefied and painful. Dress the wound in the ordinary way.

The operations made in the plague hospital of Rio de Janeiro during the epidemics of 1900 and 1901 numbered 642, with a mortality of 10 to 15 per cent., varying according to the number of the buboes present, their locality, and the duration of the illness before surgical intervention.

The extirpation of the buboes even in the fatal cases seemed to temporarily afford beneficial effects, so much so as to induce one to entertain the idea of a favourable prognosis. At the autopsy of cases with inguinal-femoral buboes which had been operated upon, the cause of death was found to be due to infiltration of the lymphatic glands of the pelvic cavity, owing no doubt to delay in operation or because the patient objected to operation. On the other hand, we have been able to verify the death of a patient from septic peritonitis after nearly a month's laboured convalescence, caused by evacuation of the ichorous matter of a pelvic gland opening into the peritoneal cavity. This case was one of the most typical to prove the insufficiency of the anti-plague serum, also as regards its anti-bacterial action, for we injected more than 300 ccm., and the bacilli still remained living and virulent in the necrotic focus of the gland.

All the operations have been practised in the gravest cases (pestis major), in ordinarily severe cases (multiple buboes, axillary and groin buboes, double groin and pelvic buboes, cervical, parotid buboes), and the results obtained leave no doubt as to the efficacy of the method.

After duly comparing the results obtained in the plague hospital of Rio de Janeiro from treatment by the surgical method I feel myself justified in recommending it, and in regarding the objection put forward in condemnation of the surgical plan of treating plague buboes as without foundation in fact.

And I am also persuaded that the exclusion of this method of treatment depends upon the want of clinical knowledge of the disease, and upon a strange objection of medical men to surgical intervention in ailments of the lymphatic system generally and not for scientific reasons.[1]

[1] The surgical treatment proposed by myself has also been applied with success in plague cases in Naples in 1902 and 1903, after the serum (Yersin-Roux) treatment had proved useless.

In none of the individuals operated upon was any inconvenience subsequently caused by extensive extirpation of the glands. The patients left the hospital in about fifteen days after operation and ready to recommence their occupations at an early date.

By examining the temperature charts of typical plague cases treated by different curative methods, one observes that in bubonic cases operated upon, the fever falls at once *by crisis*, and at the same time all the grave symptoms of intoxication (delirium, tachycardia, dyspnœa) cease, whilst they continue for a long time when the treatment is limited to serum only.

In order to demonstrate yet further the efficacy of surgical intervention as the rational treatment of plague, in several cases of double buboes we extirpated the glands from only one side, applying at the same time the serum treatment. The improvement in the patients was at once evident after the extirpation of only one bubo, but on the following days the temperature rose again over 39° C., and followed the sub-typhoid type, with tachycardia and delirium. When the treatment was completed by the extirpation of the second group of buboes, the symptoms of intoxication ceased in a few hours, and the patient became convalescent.

Conclusions.

(1) In the plague hospital of Rio de Janeiro, the mortality of the patients treated with anti-plague serum only remained between 25 to 50 per cent., according to the cases and the quality of the sera inoculated. But we must remember that in the statistics in favour of serum therapy are included the mildest cases which ordinarily recover without cure. The estimation of the curative effect of the specific anti-plague sera is very uncertain also on account of extreme variableness of the dose in identical cases. Serum is absolutely of no efficacy in the septicæmic type of plague (infection by the gastro-intestinal way), and in pestis pneumonica, where without doubt it is more necessary to administer a substance capable of rendering innocuous the specific virus in the body of the patient.

(2) The inefficacy of the anti-plague sera which are actually used as a means of cure depends on the deficiency of their anti-bacterial power, and on the almost absolute want of anti toxic substances, because the animals used for the preparation do not readily assimilate and destroy the poisons of the plague bacillus, and do not accumulate in their blood sufficient quantities of anti-bacterial and anti-toxic substances for the cure of man.

On this account we obtain the best results for the serum therapeutics in plague from immunising mules, asses, or oxen, and inoculating them with the juices of the pathogenic products of the animals infected with plague, instead of artificial cultures.

(3) With the artificial sera of Hayem and Fodor we obtained also favourable results, but the inconvenience of inoculating large quantities of liquid directly into a vein induced us to limit the application of such a curative method to a few cases.

(4) With the intravenous inoculations of corrosive sublimate, proposed by Bacelli [29], the mortality oscillated within almost the same limits as those afforded by the specific sera—that is, between 30 to 40

per cent.—and, as I have already indicated, this curative method must be recommended before any other when we have not at our disposal freshly prepared sera, and when it is not possible to practise surgical treatment at a sufficiently early period in the illness. The corrosive sublimate acts as an efficient stimulus of the phagocytosis (Gaglio) [30], and offers the advantage that it is within every physician's reach even in regions where we cannot always hope to have at our disposal other medicaments difficult to prepare, such as sera. It is known also that mercury fixes itself by preference in the lymphocyte of the lymphatic glands and in the plasma, and in this manner sets up an unfavourable condition for the development of the plague bacilli in the tissues which this infecting germ prefers. For this reason I think the use of mercuric chloride preferable to carbolic acid, recommended by Mr. Seymour [31], especially in cases in which we can already demonstrate the presence of the bacilli in the blood.

(5) In grave cases (pestis major) in which it is not possible to expect a success from the serum therapeutics or from other local cures, there remains as the only rational resource the extirpation of the buboes.

I consider the extirpation of the bubo preferable to all the other local cures.

The simple incision of the bubo, with the evacuation of the pus has good results, but has not so rapid and durable an effect in arresting the course of the infection as when the bubo is completely extirpated.

Compresses of tepid disinfecting solutions (mercuric chloride, carbolic acid) are indicated locally, in order to limit the diffusion of the process when the bubo is removed and the injection of those solutions (mercuric chloride, 1 in 1,000, carbolic acid, 1 to 2 per cent.) around the area occupied by the bubo, especially when from the surrounding œdema and from the adhesive periadenitis we may infer that there is a combined action of the plague bacillus, together with other bacteria (*streptococcus, diplococcus*). It is also useful to have recourse to these means when the radical operation is not possible or too long delayed.

All the other local treatments must be considered more pernicious than useful, because they cannot exercise any action on the bacilli located in the tissue of the lymphatic gland, as we thereby lose precious time.

It is an unpardonable mistake to wait for the suppuration of the bubo before we decide upon surgical intervention, because the patient succumbs either on account of the rapid progress of the infection, or from the effect of the toxic products *which cannot be neutralised by the curative action of the serum.* We must not take into serious consideration either the constitution of the individual, nor pay too much regard to the resistance of the patient; whilst the bubo remains the probability of cure becomes always more remote, the operation has to be performed under much graver conditions, because the extension of the infiltration destroys the anatomic relations of the region, and complications, such as phlebitis, lymphangitis, ichorous infiltrations along the muscular sheath, with the danger of an effusion into the cavities, are more likely to ensue.

If it is not possible in the patient's house to provide for the surgical treatment, we can at least give intravenous inoculations of specific serum (20 to 40 ccm.) or of mercuric chloride (1 to 2 centigram of the Bacelli solution), and subsequently bring the patient under better conditions to the hospital.

I may affirm with all confidence that if plague is treated by the above indicated method, the mortality is reduced to the conditions and to the limits of the other infectious and contagious diseases generally considered much less grave in their effects.

The opinion of Scheube [32], who does not think the application of the surgical treatment during an epidemic to be feasible owing to the great number of patients, is scarcely sound, especially when we consider that in time of war surgical operations of much greater severity are rapidly and extensively practised.

Surgeons should be substituted for physicians in our plague hospitals during times of epidemics.

THE ANATOMY OF THE BITING FLIES OF THE GENERA *STOMOXYS* AND *GLOSSINA*.

By Lieut.-Colonel G. M. Giles, I.M.S. (Rtd.).

(*Continued from p.* 219.)

The parovaria (fig. 9) are two long, somewhat convoluted tubes, the larger distal ends of which are attached to the branches of the oviduct near to the point, where they loose themselves in the stroma of the ovaries. They then pass backwards into the ovipositor, and then turn forwards again to their termination in the common oviduct. They have the same trabecular structure as the paragonia, but the trabeculæ and the nuclei of their internodes are much larger, and a comparison of fig. 9, Plate I., with fig. *b*, Plate II., shows that they also present resemblances in structure to that of the younger ovarioles. They appear to secrete a coagulable fluid similar to that of the paragonia. The remaining accessory structures are the spermothecæ or receptaculæ seminis, of which there are three, each of which (Plate II., fig. *b*.) consists of a dense chitinous sac supported in a cellular mass like an acorn in its cup.

The chitinous membrane is fenestrated, as will be seen in fig. 2, and the ducts are supported by a spiral fibre somewhat like that of a trachea, but much coarser.

Only one coitus takes place between the sexes, and in these sacs sufficient semen is stored on that occasion to last the life of the female.

The ovipositor is quite of the usual type. Lieut. Tulloch describes it as follows:—

"The ovipositor consists of three cylindrical segments of thin chitin, which usually lie telescoped inside the abdomen. There is also a single external flap of dark chitin, which lies folded upon the ventral surface of the fly. When the ovipositor is extruded, by squeezing the abdomen, the receptacula and uterus are pulled down with it and can be seen through the transparent walls. The upper segment has three longitudinal rods of chitin, two dorsal and one ventral. The next is similar, but the last has the two dorsal plates only. The external flap, which is probably the ventral rib of the last segment, is roughly quadrilateral, and has no divergent prong-like processes arising from its free hinder border."

Within the ovipositor is a complicated system of circular and longitudinal striated muscles, which perform the actions of protrusion and retraction.

The male organs of *Glossina*, as far as their histology is concerned, present no notable differences from those of *Stomoxys*, but according to Prof. Minchin, the paragonia are more of the usual type, being distinct from each other throughout. Those of the female, on the other hand, depart entirely from the usual fly-type, being modified to meet the peculiar plan of reproduction of these insects which give birth not to a multitude of eggs but to a very limited number of larvæ. Owing to this, the common oviduct or uterus is of great size, and to expel the large full-grown larvæ the ovipositor is provided with muscles, which, although on the same plan as those of *Stomoxys*, are so enormously developed that a section of this part of the body on a casual glance looks much like one of the thorax of an ordinary fly. Prof. Minchin's description runs as follows:—

"The female genital organs differ considerably in appearance, according as they are in the gravid or non-gravid condition. In the course of my dissections I have only found one female in the latter state. In the later periods of gestation the condition of the female is obvious externally, but females which do not appear to be gravid are found on dissection to have a small larva in the uterus.

"The female organs (fig. 35) consist, like those of the male, of paired and unpaired portions. The former comprise the ovaries, the receptacula seminis and their ducts, and the

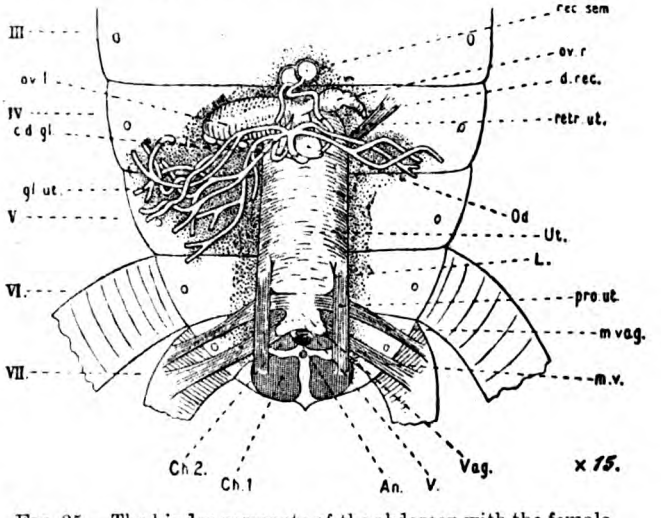

Fig. 35.—The hinder segments of the abdomen with the female genital organs of Glossina *in situ*, dorsal view. *rec. sem.*, receptacula seminis; *ov. r.*, *ov. l.*, right and left ovarioles; *d. rec.*, duct of the right receptaculum seminis; *gl. ut.*, uterine glands (the greater number of these have been removed); *c. d. gl.*, their common duct; *retr. ut.*, retractor muscle of the uterus; *Od.*, oviduct; *Ut.*, uterus; *L.*, hinder extremity of the larva, causing a bulge in the uterus; *pro. ut.*, protractor uteri, attached to the chitinous plate (*Ch.* 1); *m. vag.*, muscle (dilator vaginæ?) passing from the vagina to the tergum of the seventh abdominal segment; *m. v.*, muscle passing from the paired chitinous plate (*Ch.* 2) on each side of the vulva to the seventh tergum; *Vag.*, vagina; *V.*, vulva, the anterior margin of which is shown by a dotted line; *An.*, anus; *Ch.* 1, *Ch.* 2, paired chitinous plates. (After Tulloch.)

uterine glands; the latter are the oviduct, uterus, and vagina. The female system of organs is considerably modified from the condition usually found in insects, in relation to the fly's peculiar method of reproduction.

"The ovaries are reduced to a single pair of ovarian tubes or ovarioles, one on each side of the body (figs. 35 and 36, *ov. r.*, *ov. l.*). Each ovariole shows only a small number of egg-chambers, not more than four or five. The lowest chamber is very much larger than any of the others, and contains a large ovum. When this ovum is comparatively small, the other egg-chambers are in a line with it (fig. 6,

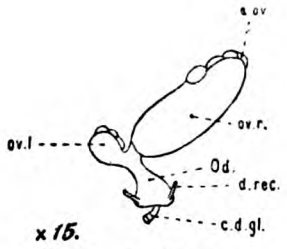

FIG. 36.—The ovarioles and oviduct of a non-gravid female Glossina. *a. ov.*, apex of right ovariole; other letters as in the preceding figure. The very large ovum in the right ovariole has pushed the oviduct over towards the left side of the body.

ov. r.), but as the ovum grows larger it grows past the other egg-chambers, so that they appear attached to the side of the ovum (fig. 35, *ov. l.*, fig. 36, *ov. l.*, *ov. r.*).

"The two ovarioles are always asymmetrical, owing to the fact that the ova in the lowest egg-chambers reach full growth on each side alternately, so that if there is a large ovum on the left, there will be a smaller one on the right, and *vice versâ*. The largest ovum I have seen was from a non-gravid female (fig. 36, *ov. r.*), and was probably nearly, if not quite, full-sized.

"The two ovarioles open into the short, broad oviduct (figs. 35 and 36, *od.*), which widens out at its lower end to open into the uterus slightly behind the proximal end of the latter.

"At its distal-expanded end the oviduct receives right and left the two ducts (*d. rec.*) of the receptacula seminis. The latter (*rec. sem.*) are small spherical bodies of a bright orange-yellow colour, surrounded by a whitish, transparent envelope. Examination of the receptacula stained and mounted in Canada balsam shows that the clear envelope is an epithelium of large cells, surrounding a thick chitinous membrane which gives these organs their peculiar colour, and which is too opaque for the contents to be seen except in sections, by which method the receptacula are seen to be filled with spermatozoa. The two receptacula are firmly attached to one another. From each comes off the slender white duct, slightly convoluted. The ducts are perfectly distinct from one another, and open, as described above, into the lower end of the oviduct.

"Immediately below the opening of the oviduct into the uterus, a small tube debouches into the latter by a median dorsal aperture. This is the common duct of the uterine glands (figs. 35 and 36, *c. d. gl.*). After a short course it branches right and left into tubes, which branch again repeatedly, forming a great number of glandular tubes, which differ markedly in the gravid and non-gravid condition. In the latter state the gland-tubes are relatively few and very slender. In the gravid condition, on the other hand, the tubes are very numerous, forming a tightly packed mass filling up the posterior end of the abdomen, and requiring to be pulled away to show the other parts of the generative system; further, the individual tubes are much thicker, and when stained and mounted, they take up the stain very deeply and appear very opaque. There can be no doubt that these glands serve for the nourishment of the larva in the uterus.

"The uterus (*Ut.*) is a large thimble-shaped organ attached to the body-wall by a number of muscles. Two retractors (*retra. ut.*) run forwards from the proximal end. There are two pairs of protractors, one dorsal, the other ventral; the former (*pro. ut.*) start from the sides of the uterus and pass backwards to a pair of chitinous plates (*Ch.* 1) at the posterior end of the body. The wall of the uterus is beset by a very large number of small tracheal tubes (not shown in the figure), and is thick in the non-gravid condition, but becomes thinner when stretched by the growth of the contained larva. In all gravid uteri that I have seen, the two papillæ at the hinder end of the larva cause a bulge in the lower end of the uterus (fig. 35, *L.*). When the larva reaches a certain size, the rings of its segments become plainly visible through the wall of the uterus; they could not be seen in the uterus drawn in fig. 35; but in another, slightly larger, they could be seen distinctly."

The writer is under the impression that there are three and not two receptacula seminis, but the opinion is derived from series of sections and not from dissection.

Only four or five larvæ are produced by each female in a season, so that the insect is much less prolific than even certain mammals, and it can scarcely be doubted that this circumstance offers the best hope of their destruction, as it is obvious that under such conditions the destruction of an adult is a much more serious blow to the chances of multiplication of the race than that of many score of the ordinary oviparous flies. It seems, then, that much might be hoped for from the systematic destruction of the adult flies, and in view of the terrible ravages of sleeping sickness, it cannot be denied that the object is one on which considerable expenditure of money and energy would be more than justifiable.

AFRICAN RELAPSING FEVER.

Koch finds that although quinine is useless in relapsing fever, the trypan-red is of some value. Seeing that immunity is conferred by one attack, Koch is led to hope that some form of serum treatment will be found efficacious. Whilst travelling in an endemic centre of the disease, Koch found that by pitching tents on fresh ground, apart from the old-standing shelters, relapsing fever could be avoided, as the tick only prevails in the dry, long-built shelters on the caravan route.

"Annales de l'Institut Pasteur," Paris, vol. xx., No. 3.

THE FRENCH REPORT ON YELLOW FEVER.

Marchoux, E., and Simond, P. L., in the final instalment of the Report on Yellow Fever by the French Commission to Brazil, go fully into the part played by infant infection in maintaining the endemicity of yellow fever. An outbreak of yellow fever leaves the community almost entirely immune to the disease. Those who escape at the time of the epidemic may subsequently develop the disease in the form of sporadic cases, but were it not for new-born infants the non-immunes would soon be exhausted. Owing to the mildness of the disease in children the affection may escape notice, and because the adults are not attacked the disease is supposed to have died out, whereas in reality it is being continued amongst the infants. This possibility serves to explain how non-immune aliens contract the disease on arrival in the yellow fever zone. The apparent immunity of the negroes to yellow fever is no doubt explainable on the assumption that they had a mild type of the disease in infancy and thereby became protected against subsequent seizure.

Business Notices.

1.—The address of the JOURNAL OF TROPICAL MEDICINE is Messrs. BALE, SONS & DANIELSSON, Ltd., 83-91, Great Titchfield Street, London, W.

2.—All **literary communications** should be addressed **to the Editors.**

3.—All **business communications** and **payments,** either for subscriptions or advertisements, should be sent **to the Publishers** of the JOURNAL OF TROPICAL MEDICINE. Cheques to be crossed The Union Bank of London, Ltd.

4.—The Subscription, which is **Eighteen Shillings** per annum, may commence at any time, and is payable in advance.

5.—Change of address should be promptly notified.

6.—Non-receipt of copies of the Journal should be notified to the Publishers.

7.—The Journal will be issued on the first and fifteenth day of every month.

Reprints.

Contributors of Original Articles will be supplied FREE with six copies of the Journal if a request accompany the MS. If reprints are required they will be supplied by the publishers, if the order is given with remittance when sending the MS. The price will be as below:—

50 Copies of four pages, 5/-;
100 „ „ 6/-;
200 „ „ 7/6;
50 Copies beyond four up to eight pages, 8/6;
100 „ „ „ 11/-;
200 „ „ „ 14/6.

One page of the Journal equals 3 pp. of the reprint.

If a printed cover is desired the extra cost will be for 50 Copies, 5/6; 100 Copies, 6/6; 200 Copies, 7/6.

LIVERPOOL SCHOOL OF TROPICAL MEDICINE—MEMOIR XVIII.

REPORTS OF THE EXPEDITION TO THE CONGO, 1903-5. By the late J. Everett Dutton, M.B.Vict., and John L. Todd, B.A., M.D., C.M.McGill, with Descriptions of Two New Dermanyssid Acarids by Robert Newstead, A.L.S., F.E.S., &c., and "The Anatomy of the Proboscis of Biting Flies," by J. W. W. Stephens, M.D.Cantab., and Robert Newstead, A.L.S., F.E.S., &c. March, 1906. (London: Published for the Committee of the Liverpool School of Tropical Medicine by Williams and Norgate, 14, Henrietta Street, Covent Garden.) Price 7s. 6d. net.

I.—GLAND PALPATION IN HUMAN TRYPANOSOMIASIS.

Dr. Todd and the late Dr. J. E. Dutton, in their 1904 report of their expedition to the Congo, drew attention to the usefulness of examining the fluid extracted by gland puncture as a routine method of diagnosing the presence of trypanosomes in the human body. The prevalence of enlargement of glands in trypanosomiasis is not only a marked feature, but its universality and constancy are diagnostic signs, and in the report now before us an enquiry into the practicability and reliability of this method of demonstrating the presence of trypanosomes in the human body has been gone into fully.

Gland Puncture.

The technique of gland puncture is simplicity itself, although requiring care and some experience before satisfactory results are obtained with certainty. An ordinary hypodermic syringe, after the instrument and skin have been rendered aseptic, is plunged into the substance of an enlarged subcutaneous gland held steadily in place between thumb and forefinger.

To prevent scattering the tiny quantity of fluid in the barrel of the syringe by the sudden influx of air when the needle is withdrawn, release the plunger, which had been drawn out to full extent, before the needle is withdrawn from the skin. The drop of fluid in the syringe is expelled from the syringe on to a slide, a cover-glass superimposed, and the preparation, ringed with vaseline, is examined at once. Examination of a first preparation of gland fluid is frequently negative. When glands are particularly soft the fluid obtained is apt to be glairy and pus-like, and therefore rarely contains trypanosomes. The glands usually selected for the examination are those of the post-cervical region.

Comparisons of Clinical Methods of Demonstrating Trypanosomes.

Successful examination may be estimated from several standpoints. When, however, the first test was unsuccessful, further examination succeeded in demonstrating the presence of parasites; the result was as follows:—

	Blood			Gland Juice	Cerebro-spinal Fluid
	Fresh Coverslip Preparations	Centrifugalised	Total		
Percentage of successful examinations	13·3 %	41·2 %	49·2 %	90·4 %	59·6 %
Number of repeated successful examinations	2	1	—	17	No second examination was successful

It will be seen that according to the table the examination of the cerebro-spinal fluid gave moderately constant results only; but when a closer analysis is made it is found that it is in advanced cases of the illness that the examination of the cerebro-spinal fluid gives a high percentage of positive results. By "advanced" cases are meant persons obviously ill; in "early" cases no general symptoms are presented, and the disease is unsuspected by friends.

	Blood			Gland Juice	Cerebro-spinal Fluid
	Fresh Coverslip Preparations	Centrifugalised	Total		
Advanced Cases					
Percentage of successful examinations	20·6 %	53·8 %	57·3 %	95·6 %	96·6 %
Early Cases					
Percentage of successful examinations	8·6 %	25 %	31·4 %	98·5 %	13 %

As trypanosomiasis advances, the glands of all the superficial groups diminish in size, so much so that it is occasionally difficult to find a gland large enough to puncture. As, however, it is during the early stages of the disease that diagnosis by other than clinical features are called for, there can be no doubt that gland puncture is by far the most efficient method of demonstrating the presence of trypanosomes in cases of trypanosomiasis.

Glandular Enlargements an Index of Trypanosoma Infection.

As the result of extensive examinations of many people in many villages, Drs. Todd and Dutton came to the conclusion that in the great majority of cases enlarged cervical glands in apparently healthy negroes means trypanosomiasis in an area where "sleeping sickness" is prevalent.

The region of the body examined for gland enlargement was the posterior cervical group, just in front of the anterior border of the trapezius. In this situation usually three or four middle-sized glands (diameter 1 cm.) lie at the base, or one or two glands of smaller dimensions are met with at the apex of the triangle, where trapezius and sternomastoid muscles meet at their occipital insertions. Occasionally, however, the whole of the posterior triangle of the neck is literally filled with enlarged glands.

Another clinical point of significance is that "unless the glands of apparently healthy persons were enlarged, juices from them did not contain trypanosomes."

The conclusions arrived at by Drs. Todd and Dutton are that (1) as a rule enlarged cervical glands, without obvious cause, do not occur in districts from which trypanosomiasis is absent; (2) every negro with enlarged glands must be considered, until the contrary is shown, to be a case of trypanosomiasis; (3) early cases of trypanosomiasis have enlarged glands, and will therefore be detected by gland palpation; (4) good results may be expected from the serious application of quarantine measures dependent for their efficiency upon cervical gland palpation.

Prevalence of Trypanosomiasis.

By a series of maps the distribution and spread of sleeping sickness in the Congo Free State is clearly shown, and several interesting facts are dealt with by the same observers under this head. The distributing factor, *Glossina palpalis*, is found everywhere along the route followed by sleeping sickness disease, and it is significant to note that there are several districts in which Glossinæ are found in which there is no sleeping sickness; in other words, the disease may be expected to spread corresponding with Glossina prevalence. It seems from all available evidence that sleeping sickness has spread, and is spreading, more widely as increased facilities of communication multiply; yet it is a mistake to believe that previous to 1885, when the Congo Free State was founded, sleeping sickness was so limited in its distribution as we are apt to imagine. Before the inroad of Europeans in 1884 the highest point in the Congo known to be infected by sleeping sickness was at the town of Bumba, situated on the northern bank of the Congo at the point where the great bend of the river makes its most northerly point, and about 700 miles in a straight line inland from the mouth of the river. In all the districts between Bumba and the mouth the natives knew and had a name for the disease, whereas in the Upper Congo reaches above Bumba the disease is, or was until recently, quite unknown, and the natives either coin a new word to describe it or use a name borrowed from neighbouring tribes. In 1888 the first step towards suppression of the slave trade began, expeditions were sent in all directions, and soldiers and labourers from the infected districts of the Lower Congo travelled upwards along the Kasai River, and penetrated far to the eastward, carrying with them sleeping sickness. In addition to the traffic from west to the east, that is, from the infected districts near the mouth of the river inland, labourers were brought from the upper reaches of the river to work near the mouth, who, when their term of engagement ended, returned to their native places, thereby no doubt spreading infection to many new centres.

The evidence obtainable is, however, not sufficiently unanimous or positive to assert that sleeping sickness did not exist in the area between the Upper Congo and Lake Tanganyika, but that there has been a wider distribution of the disease in many directions since the traffic between Central Africa and the mouth of the Congo has been increased is certain. One point in the investigation seems fully brought out, namely, that when sleeping sickness has once gained a hold on a district, there is no evidence that the disease ever wholly disappears.

"A New Dermanyssid Acarid Found Living in the Lungs of Monkeys (*Cercopithecus schmitdi*) from the Upper Congo." By R. Newstead, A.L.S, and J. L. Todd, M.D.

In the district between Lusambo, in the upper reaches of the Kasai River, and Kasongo, in the Upper Congo, a parasite named *Pneumonyssus duttoni, n. sp.*, has been found in eleven monkeys of the *C. schmitdi* species. The parasite has not been met with amongst monkeys of other species living in the same district, so that it would seem that the "funny type" (*C. schmitdi*) of monkey is alone affected. Female acarids only have been found in the lungs of these monkeys, and although no eggs have yet been seen,

larvæ and partially matured acarids were found in the trachea and bronchi of the monkey, from the larynx down to the second and fourth, and even fifth branchings of the bronchi. The species of acarid closely resembles *P. simicola* found in the lungs of a Javanese monkey, but differs in the possession of an additional pair of stigmata, and a large dorsal scutum or shield.

Mr. Newstead also describes another new Dermanyssid acarid, which he has named *Pneumonyssus griffithi, n. sp.*, obtained from the lungs of the Rhesus monkey (*Macacus rhesus*). The parasite has been named after its discoverer, Dr. C. A. Stanley Griffiths, The new acarid was first found in a series of six adult Indian Rhesus monkeys, belonging to the Royal Commission on Tuberculosis, which were killed for examination, on account of having been in contact with a monkey suffering from spontaneous tuberculosis.

"The Anatomy of the Proboscis of Biting Flies. By J. W. W. Stephens, M.D., and R. Newstead, A.L.S.

The species of fly examined was the tsetse-fly, *Glossina palpalis*, R. D., and the description refers to the female of that species for the most part. In this erudite description many hitherto unsettled points in the anatomy of the labella, labium, labrum, hypopharynx, and the mechanism of the proboscis are dealt with and apparently settled. Many excellent drawings of the proboscis of the Glossina accompany the descriptive details.

THE MEETING OF THE BRITISH MEDICAL ASSOCIATION AT TORONTO.

THE visit of the British Medical Association to Toronto promises to be a success, judging from the large number of medical men who are journeying from Britain to attend the meeting. The Association has previously met in Montreal, but Toronto is the furthest distant point from "home" at which British medical men have assembled. Situated on the shores of the Lake Ontario, the focus of several railway lines, and adjacent to important agricultural districts, Toronto has increased of late years to a commercial city of great importance. The public buildings and the wide, handsome streets of Toronto are held in high estimation by the citizens, who are justly proud of their flourishing city. To medical men, however, the University buildings and the history and development of the University are sure to prove more interesting than either the natural beauties of the district or the municipal and commercial buildings of the city itself.

The movement which resulted in the establishment of a Provincial University in Ontario (then Upper Canada) dates from the closing years of the eighteenth century. In 1797 the Governor of the Province, at the request of the Legislative Council and House of Assembly of Upper Canada, petitioned His Majesty George III. to appropriate "a certain portion of the waste lands of the Crown as a fund for the establishment and support of a respectable grammar school in each district of the Province, and also of a college or university." The petition was granted, and the Executive Council, in conjunction with the Judges and Law Officers of the Crown in the Province, were instructed to report on the manner and extent of the appropriation. Their report (1798) recommended: (1) The immediate establishment of a grammar school at Kingston, and another at Newark (now Niagara); (2) the establishment of a grammar school at Cornwall, and another at Sandwich as soon as funds should permit; (3) the establishment of a University in York (now Toronto); (4) the appropriation of 500,000 acres of Crown lands for the establishment and maintenance of the four schools and University; and (5) the reservation of at least one-half the whole grant for the purposes of a University. In 1799 the appropriation of lands was made, consisting of 550,274 acres.

From 1799, the project made no progress whatever. In 1819, however, a report was drawn up by the Executive Council, looking towards a realisation of the land endowment, recommending the obtaining of a Royal Charter. In 1820 provision was made by law for the representation of the proposed University by a member in the House of Assembly. In 1825, the exchange of a portion of the original grant of lands for an equal portion of the more valuable "Crown Reserves" was proposed, and was carried into effect in 1828. In 1827 the Charter was granted for the University under the title of the "University of King's College," and the necessary authority was given for the exchange of the original endowment lands above referred to. By this Charter, the teaching, examining and management were entrusted to a corporation, consisting of the Chancellor, President, and Professors.

By the Baldwin Act, the name of the institution was changed from King's College to that of "University of Toronto." Its secular character was made perfectly clear; not only were all religious tests abolished, as regards the Faculty, students and graduates, but it was also provided that neither the Chancellor nor any of the Governor's representatives on the Senate should be "a minister, ecclesiastic or teacher, under, or according to, any form of profession of religious faith or worship." The Faculty of Divinity was abolished, as also the right to confer degrees in Divinity.

In 1887 an Act known as the Federation Act was passed, whereby the various denominational institutions were united with the University of Toronto. Under this Act, Victoria University (Methodist), St. Michael's (Roman Catholic), Knox College (Presbyterian), Trinity and Wycliff Colleges (Anglican), have entered into confederation with the University of Toronto, which latter has also, under the Act, a teaching Faculty of Arts and Medicine. Latin, Greek, Ancient History, English, French, German, Oriental Literature and Ethics are taught both by University College and Victoria University, and the other colleges mentioned, while St. Michael's co-operates in teaching Modern History and Philosophy. By this arrangement, largely one of convenience, all other subjects in Arts and all subjects in medicine are left to the teaching Faculty of the University of Toronto. Both the University of Toronto and University College are supported from a common fund derived from endowments and other sources. Various institutions, such as the School of Practical Science, the Agricultural

College, &c., have entered into affiliation with the University, and enjoy representation in the Senate, which in turn prescribes their curriculum and examines their students.

The architectural beauties of Toronto University are well known. The main building is a handsome structure in the Norman style of architecture, and its classic main entrance is without a rival on the American continents. This building was badly gutted by fire some years ago, but its restoration was thorough and complete, and the building now presents a finer appearance than it did before the conflagration. The University campus is dotted with a series of buildings, each housing a certain branch of the University's work.

Report.

REPORTS ON THE HEALTH AND SANITARY CONDITION OF THE COLONY OF HONG KONG FOR THE YEAR 1905. (Hong Kong: Noronha and Co., 1906.) Pp. 140.

The estimated total population of Hong Kong, including the adjacent territories of Kowloon (old and new) and the military and naval commands, amounts to 377,850. The birth-rate is given as 3·40 per 1,000, and the death-rate as 17·45 per 1,000. The disproportion between the birth- and death-rates which seem unaccountable with a rapidly increasing population is attributable to the fact that the Chinese women in the colony are few in number, and that the wives of the Chinese do not, as a rule, dwell in the colony.

Malaria.—During the past three years the total number of deaths amongst Chinese attributable to malaria has diminished by half, compared with the returns of the previous three years. Amongst Europeans resident in Hong Kong the deaths from malaria during 1905 fell to four, compared with 29, 33, and 32 during the three years 1900-1902.

Dr. J. Bell, the Superintendent of the Civil Hospital, remarks: "There can be no question that the war waged by the authorities against the mosquito has given as good results here as anywhere else." One district in the outskirts of the city of Victoria, which used to supply very bad cases of malaria both in Europeans and their Chinese servants, has not supplied a single admission for 1905. The malignant variety of malaria is much the most common variety and the disease is more prevalent in the latter half of the year.

Dysentery.—The bacillary form of dysentery outnumbered the amœbic variety in a proportion of about two to one. The bacillary form of dysentery would appear to confer an immunity against further attacks, but not against the amœbic type; one patient suffered in January from the bacillary form, but returned to hospital in October of the same year with dysentery of the amœbic type.

The Superintendent of the Civil Hospital states: "I think the amœbic variety is the less prevalent and fortunately so, as it is a much more serious complaint, more difficult and more tedious to treat—in some cases I doubt whether they are ever cured by anything short of removal out of the Tropics." In regard to the spread of dysentery the Superintendent writes: "The mobile form of the amœbæ die rapidly in the stool, but the encysted form are much hardier, and must be the means of spreading the disease. The question for the future to solve is whether they do not undergo some change in a suctorial insect, and so get passed on to man in a manner similar to malaria."

Plague.—During 1905 the plague cases numbered 304 and the deaths from the disease amounted to 287—a death-rate of 94·1 per cent. These are the smallest figures in regard to plague since 1894, except during the years 1895 and 1897, when the cases of plague numbered 44 and 21 respectively. Of the cases, 73·16 were of the bubonic type, 25·0 per cent. were of the septic type, and 1·84 of the pneumonic variety. Dr. W. M. Koch, the officer in charge of the Infectious Diseases Hospital, remarks: "Of the bubonic variety 85 per cent. died; of septic cases, 60 per cent. It will be noticed that the bubonic variety was the more fatal."

Rat Plague.—"The amount of rat plague," Dr. William Hunter, the Government Bacteriologist, remarks, "would appear to be increasing in the colony. About 5 per cent. of the rats examined during 1905 were found to be plague-infected." He adds: "Arguing from the dictum no rat plague, no human plague, our chances of freeing the colony from this exotic are but small for some years to come." Dr. Hunter is more and more impressed with the part played by the rat in the spread of plague, and experience shows that "Danysz's virus as an agent for the wholesale destruction of rats has been a complete failure." Experience with Yersin's serum in plague during 1905 in Hong Kong is not encouraging.

Relapsing Fever.—Three coolies, on their way to North China from South Africa, were found to be suffering from relapsing fever, and the spirillum was found in their blood. In connection with these cases, an important fact was noted. The office boy of the hospital, to which these cases of relapsing fever were admitted, was attacked by the disease. The boy saw the patients frequently, and helped to coax mosquitoes to feed on them, and assisted in procuring films, but had nothing else to do with the patients in the way of nursing, &c., yet he passed through a typical attack, and the spirochætæ were found in his blood. The question of how he contracted the disease is a difficult problem to solve, but the fact that he did so under the circumstance is well worth further investigation. Relapsing fever is prevalent in North China, but is not endemic in Hong Kong.

Malta fever has not been proved to be present in Hong Kong as an endemic infection.

The experiments and observations on beri-beri by Dr. Hunter will be specially dealt with in a future issue.

This report, which will be dealt with in the Colonial Reports, is full of interest, and contains many original investigations and observations.

Reviews.

NUTRITION AND DYSENTERY. By Lieutenant-Colonel U. N. Mukerji, M.D., I.M.S., Retired. (Calcutta: S. K. Lahiri and Co.)

It is pleasant to find that this well-known native member of the Indian Medical Service, although retired

from the service, has no intention of retiring also from active scientific work, and in the present little volume we have the results of a ripe experience in dealing with that most troublesome tropical malady, dysentery.

Dr. Mukerji's view is that dysentery is primarily a trophic malady, the main predisposing causes of which are dietetic errors; in other words, that the dyspepsia of dysentery is the cause and not the consequence of the disease in the stage in which it usually comes first under the notice of the medical practitioner.

Nor is this view in any way incompatible with the results of modern parasitological investigations which have subdivided dysentery into protozoal and bacterial forms, and the latter into a number of varieties in which Shiga's bacillus and a variety of other strains of microbe are found in the motions, for most who have had much to do with the clinical side of dysentery will agree that it is almost impossible from the bedside point of view to predicate what micro organisms will be found by the bacteriologist, and that it is highly probable that it is rather the disease that affords them their opportunity than that they are the *causa causans* of the disease. On this account the reader must not expect to find more than casual mention of the microbiology of dysentery, which has, of course, only an indirect connection with the point of view dealt with by Dr. Mukerji.

There is no better field for the study of dysentery and the effects of diet on nutrition than an Indian jail, as the Indian medical officer acts not only as the physician, but also as governor of these institutions, and is wisely given a very free hand in the management of the dietary of the prisoners.

The service will, we feel sure, be grateful to an old brother officer for many useful hints on the management of prisoners, and the author's intimate knowledge of Indian habits of life, and their bearing on health, will make the book a most interesting one to all who practise in our great dependency. Nearly half the book is occupied with the results of a laborious investigation of the amount of urea excreted in a group of prisoners from March to July—the monthly diet scale being given in a preliminary table, but we fail to find any summing up of the conclusions the author draws from the tabulated results.

Col. Mukerji has a very high opinion of the value of the inunction of oil as a protection against chills, and hence in diminishing the incidence of dysentery, and the reviewer recalls that although in the United Provinces it has been found that a liberal provision of blankets is equally effectual, an issue of oil for this purpose to the "old and infirm" prisoners was attended with most beneficial results.

Here and there peculiarities of diction may be noticed, only natural to an author who writes in other than his mother tongue, but we doubt if any European could be mentioned who would be capable of writing as clearly in Hindustani or Bengali, and the construction will present no difficulties to any one who has lived in India.

Remembering the difficulties that beset the typographer in India, the book has been turned out by the publisher in a creditable fashion, though occasional misprints may be met with.

SCIENTIFIC MEMOIRS. By Officers of the Medical and Sanitary Departments of the Government of India. "On a Parasite found in the White Corpuscles of the Blood of Palm Squirrels." By Captain W. S. Patton, M.B., I.M.S. (Calcutta: Office of the Superintendent of Government Printing, India, 1906.)

Captain Patton's conclusions are as follows: It will be seen that the description of this parasite agrees in every detail with that of a hæmogregarine. The parasite is highly specialised in that it selects the large mononuclear leucocyte for its host. Though closely related to *Leucocytozoon canis* (James), it differs in not having a cytocyst and in possessing a tail. I therefore propose provisionally naming it *Leucocytozoon funambuli.*

As in the case of *Hæmogregarina gerbilli* (Christophers), no developmental forms were found in the organs and the infection remains unaltered for long periods. The squirrels, though harbouring two parasitic worms, were to all appearances as active as the Madras species. It is particularly interesting to note that trypanosomes were never found in the blood of the Kathiawar squirrel, which seems to point to a localised distribution of the blood parasites in very closely related mammals.

Correspondence.

To the Editors of the JOURNAL OF TROPICAL MEDICINE.

SIR,—Mrs. Scharlieb, reported in your issue of April 16th, 1906, writing about the Tropics, says: "Milk is not attainable in some places, in others it is very poor in proteids and fats."

I should be glad of some proof of the latter part of this statement, some published analyses of milks known to be unadulterated, secreted by cows in the Tropics would be useful.

Yours faithfully,

J. TERTIUS CLARKE, L.R.C.P.Lond., M.R.C.S.Eng., D.P.H.Camb.

S. D. S.,
Batu Gajah, Perak,
June 26th, 1906.

Drugs and Remedies.

PRICKLY HEAT.—The "Cyclopædia of Medicine and Surgery" recommends as a prophylactic treatment for prickly heat (miliaria) that thin, light woollen garments should be worn next the skin, the body exposed to heat as little as possible, constipation avoided, and the following lotion applied locally:—

℞.	Acidi carbolici	...	...	ʒss.
	Acidi boracis	...	...	ʒj.
	Zinci oxidi ...	...	...	ʒiss.
	Glycerini ...	...	...	ʒii.
	Alcoholis ...	...	...	ʒii.
	Aquæ q. s. ad.	...	...	ʒvi.

A dusting powder consisting of:—

℞.	Magnesii carb., acidi borici, pulv. amyli, &c. ...	...	...	aa ʒii.

When the entire body is involved the patient should

have bran, starch, or alkaline baths. Hyde recommends:—

℞.	Acidi carbolici	...	...	ʒiss.
	Glycerini	...	...	ʒii.
	Mentholis	...	...	ʒj.
	Sp. vin. rectif.	...	...	ʒi.
	Aquæ q. s., ad.	...	...	ʒviii.

to be applied locally.

Acting upon the suggestion of Professor Metchnikoff in his address on "Syphilis and its Prevention," Mr. W. Martindale, 10, New Cavendish Street, Cavendish Square, London, W., has prepared a "prophylatic ointment," suitable for instant use, and in a conveniently portable form.

Books and Papers Received.

THE first number dated July, 1906, of the *Calcutta Medical Journal*, described as the journal of the Calcutta Medical Club, is to hand. The new journal, of which Dr. K. Das is the editor, is to be published monthly at the cost of 8 annas per copy. The journal is intended for the publication of the transactions of the scientific and clinical meetings of the club and other matters of professional interest.

The following articles are among the contents:—

(1) "Ranchi, a Health Resort." By Nareshchandra Mitra, M.A., M.B. The town of Ranchi, sometimes termed "Darjeeling of the Plains," is situated on a tableland more than 2,000 feet above sea-level, and lies 240 miles south-west of Calcutta. The "season" commences in October, and extends throughout the winter. During the winter the climate is pleasant and bracing, and the isolated position of the town serves to prevent the occurrence of epidemic diseases.

(2) "Trypanosomidæ." By Gopalchandra Chatterjee, M.B. The article embodies a summary of trypanosoma met with in men and animals, nineteen in all, and three species of trypanoplasma in animals.

(3) "Oxalate of Lime in Pregnancy." By I. Mallick, M.A., L.M.S. According to this observer oxalate of lime diminishes during pregnancy.

(4) "A Large Intra-cervical Fibroid." By K. Das, M.D.

(5) "A Case of Cerebral Tumour, with no Symptoms." By C. Chackrabarty, M.B.

(6) "Angioma of the Liver." By M. Mitra, M.D., F.R.C.S.Edin.

In the journal are to be found the Transactions of the Calcutta Medical Club for February and March, 1906; and in addition reviews of current literature. We wish the journal success.

Notes and News.

THE SOUTH-WEST MONSOON.—*The Times of Ceylon* of May 25th, says: The south-west monsoon has done something more than come in like a lamb. It has crept in like a thief in the night, furtively and unannounced. It was here all the while. The monsoon arrived on May 7th, Mr. Barnard, Superintendent of the Trigonometrical Surveys, informed a representative this morning. The burst, Mr. Barnard explained, was a traditional and popular term, but was not recognised scientifically, so he was unable to say whether the monsoon had burst. "I have known the monsoon arrive where there is a perfectly clear sky," he remarked. "It came exceptionally early this year. Since the 7th of this month we have really been in the true monsoon. This is indicated by the direction of the wind, which settled down to blow in the south-west on that date."

Mr. Barnard, in speaking, had charts before him showing the direction of the wind each day. He added: "Other conditions, such as wind velocity, the temperature of the atmosphere, rainfall, &c., place it beyond doubt that we have been experiencing the south-west monsoon at least since the 7th inst. The wind was variable before that. The big rains started on the 13th inst., but the velocity of the wind was not affected at that date. The monsoons vary as to rainfall. It is too soon to say, yet, whether this is a monsoon of exceptionally light rain. In the next few days, or next week, we may have more than will make up for the deficiency."

Despite this statement, the Ceylon people do not believe that the monsoon has yet appeared. Yesterday evening certainly was monsoonish, but the usual signs of heavy rain and strong south-west wind are still absent, according to popular notions.

REPORTS from India, dated June 22nd, state that the south-west monsoon has set in throughout the whole of India, including the Punjab and Himalayas.

INDIAN MEDICAL SERVICE.—The Secretary of State has sanctioned the appointment of officers of the Indian Medical Service to be Director of the Pasteur Institute at Kasauli and Assistant Directors at the Kasauli and Coonoor Institutes, on the scale of salary sanctioned for officers of the Bacteriological Department. An addition of three officers will be made to the Indian Medical Service in order to provide for these requirements.

PESTIS SIMULANS.—E. S. Goodhue, writing from the Hawaiian Islands, on "Hawaii as a Field for Scientific Work in Tropical Medicine," states that Dr. Sinclair of Honolulu, suggests the term pestis simulans, instead of pestis minor, for a climatic bubo as defined by Cantlie. Pestis simulans is commendable "as being non-committal for cases that run a mild course of true plague in districts where plague is more or less epidemic, and where it is impossible to demonstrate the presence of plague bacilli."

INDIA has a staff of mounted army nurses. The Indian Government allows these ladies of the Indian Nursing Service thirty rupees a month for the upkeep of their horses, and free conveyance of their animals to and from active service. This corps of nurses are all ladies of good social position, and have to undergo three years' training in a general hospital before qualifying.—*Indian Public Health.*

SEA SICKNESS.—A hypodermic injection of $\frac{1}{120}$ grain of sulphate of atropia and $\frac{1}{60}$ grain of sulphate of strychnia is recommended (Girard) as a specific for sea sickness. The injection to be given at the commencement of voyage or when the sea commences to be rough.

X-RAY BURNS.—At the 337th regular meeting of the New York Dermatological Society, held November 28th, 1905, the subject of X-ray burns was taken up, and Dr. Henry G. Piffard, Emeritus Professor of Dermatology in New York University, said (*Journal of Cutaneous Diseases*) "that he had obtained the most benefit in treating these conditions from antiphlogistine, chloride of zinc, high frequency current and ultra-violet rays."

WE regret to notice the death of Lieut. Waller H. Hills, R.A.M.C., of cholera, at Cawnpore. The deceased officer was only 28 years of age, but was already extremely popular, alike with his patients and his brother officers.

Personal Notes.

INDIAN MEDICAL SERVICES.

India Office: Arrivals of Indian Medical Officers in London.—Lieutenant-Colonel W. A. Lee, Lieutenant-Colonel M. Collie, Major T. D. C. Barry, Colonel H. Hamilton, C.B.

Extensions of Leave.—Captain H. R. J. Rainier, 4 m., Med. Cert.; Captain T. H. Delaney, 6 m., Med. Cert.

Leave.

Captain W. Collinson, 1 y. general leave.
Captain W. B. Turnbull, priv. leave, 3 m.
Major W. J. Buchanan, Insp. Gen. Jails, Bengal, priv. leave, 2 m. 15 d.
Lieutenant-Colonel D. G. Crawford, priv. leave, 2 m. 27 d.

Postings.

Colonel O. Todd, R.A.M.C., to the Poona Division, and to act as P.M.O. Western Command during the absence of Colonel Trevor, on leave.
Captain H. J. Walton, Civil Surgeon, Manipuri.
Captain Knapp, services placed temporarily at disposal of Government of Burmah for employment in Jail Department.
Captain H. Ainsworth to officiate as Medical Adviser to the Patiala State.
Major C. H. James is deputed to accompany Sir Rangbir Singh, K.C.S.I., of *Patiala*, to Europe.
Mr. E. W. Payne officiates as Insp. Gen. Jails, Bengal.

Medical Notes.

GLANDULAR FEVER.

A good deal of interest attaches at the present time around this loosely named illness. In a medical man suffering from general enlargement of glands, with a series of skin lesions resembling a syphilide, Drs. Stengel, White and Evans, of Philadelphia, found that syphilis was negatived, *Spirochæta pallida* was not found, but a streptococcus resembling one met with in horses and causing glandular fever and also epidemic coryza in these animals, was detected in the patient's blood, glands, and tonsils

ISTHMIAN CANAL COMMISSION.

In his report for May, 1906, Colonel W. G. Gorgas states that during the month in question there was but one case of yellow fever in the Zone. Pneumonia continues to be by far the most common cause of death amongst the men employed on the Canal work. Malaria is less prevalent, beri-beri is decreasing, and the general health is excellent in all parts of the Zone of work.

DR. NOVY, at the meeting of the Association of American Physicians, said he had prepared a serum capable of immunising against relapsing fever, and curative if given in early stages. We anxiously await further reports on this announcement.

Recent and Current Literature.

A tabulated list of recent publications and articles bearing on tropical diseases is given below. To readers interested in any branch of tropical literature mentioned in these lists the Editors of the JOURNAL OF TROPICAL MEDICINE *will be pleased, when possible, to send, on application, the medical journals in which the articles appear.*

"The Philippine Journal of Science," May, 1906.

Tyzzer, E. E., "The Histology of the Skin Lesions in Varicella."

Whifford, H. N., "The Vegetation of the Lamao Forest Reserve."

Bacon, R. F., "The Waters of the Crater Lakes of Taal Volcano, with a Note on some Phenomena of Radio-activity."

Lewis, G. N., "Concerning Silver Oxide and Silver Sub-oxide."

The Suppression of Malaria at Ismailia.

"Suppression du Paludisme à Ismailia" (The Suppression of Malaria at Ismailia). Suez Canal Company, 1906.

The object of this pamphlet is to demonstrate the methods by which Ismailia has been completely cleared of malaria.

Ismailia, which was founded by de Lesseps in 1862, on the banks of Lake Timsah, midway between the Mediterranean and the Red Sea, has now a population of 8,000 inhabitants.

Malarial fever suddenly appeared in this town in 1877 (up to which time it was noted for its healthfulness), and spread to such an extent that in 1886 nearly all its inhabitants had suffered from ague. On several occasions the Suez Canal Company endeavoured to arrest the development of malaria at Ismaila, but without any appreciable results. In 1901 a fresh attempt was made by Prince Auguste d'Arenberg, the President of the Company, which was more in accordance with the ideas which had just then been published on the part played by mosquitoes in propagating malaria. This attempt has met with complete success, for after two years' efforts all trace of malaria has disappeared from Ismailia.

The object of these remarks is to give some general idea as to the nature of the work undertaken and of the measures adopted which enabled this result to be obtained.

[The natural and medical histories of malaria are now so well known that they need not be mentioned here.]

The researches initiated by Prince d'Arenberg, in the spring of 1901, were undertaken with a view to the possible methodical destruction of mosquitoes at Ismailia, and pending the results of these studies the prophylactic use of quinine was widely employed amongst the inhabitants, the employees who suffered from malaria were medically treated gratuitously and received full pay whilst on the sick list.

Briefly stated, the studies made during the years 1901 and 1902 were mainly directed to the four following main points:—

(1) An examination of the adult perfect Anopheles.
(2) An examination of Anopheles larvæ.
(3) An examination of ordinary mosquitoes.
(4) An examination of the ground levels, with a view to the possibility of causing the stagnant waters to disappear.

The results obtained were as follows:—

(1) The dangerous season commenced about July, and one of the first centres of production for Anopheles mosquitoes was situated to the east of the town; at the same time no Anopheles were to be found either in the European or in the Arab quarters, although the whole town was afterwards invaded. The specimens captured were afterwards found to be *Anopheles pharoensis* and *A. chaudoyei.*

(2) It was definitely proved that the reproduction of the Anopheles mosquitoes was carried out exclusively in the pools and smaller shallow ponds which were to be found everywhere, and that these were filled on the rising of the Nile, although they subsequently became dried up.

(3) The ordinary mosquitoes belonged to the genera *Culex* and *Stegomyia*, of which there were numerous species; both of these generic forms went on increasing their numbers nearly all the year round, in the cesspits, ponds, garden water-ways, and cisterns, &c., as well as in those collections of water where Anopheles larvæ were found. Experiments were made as to the destructive action of petroleum spread over the waters which contained larvæ, and also as to the quantities required for each square yard of surface to ensure efficiency of result; the effect of salt-water and of sea-water on larvæ and nymphæ showed that these could at once be killed by the water of Lake Timsah.

(4) In order to destroy the Anopheles it would be necessary to do away with all stagnant collections of water in which the larvæ of these mosquitoes had been found, and a careful survey of the town and its neighbourhood showed that this would not be a very costly undertaking.

To complete these observations, Dr. Pressat (one of the Company's surgeons) was sent specially to Italy to study the latest methods of malarial research work, and Major Ross was specially invited the following autumn to visit Ismailia and to favour the Company with his advice, which was to use every effort to *ensure total protection for Ismailia from malaria* by the destruction of all the mosquitoes, as this task appeared to be a feasible one. Immediately on the receipt of Major Ross's report, a conference was specially held to propose definite measures and the means of applying them, and it was decided that the destruction of the Anopheles was first of all to be carried into effect, and afterwards that of the other mosquitoes.

Destruction of Anopheles.—The search for Anopheles larvæ revealed three dangerous foci close to the town: (1) To the east, the marsh of Abou-Rahan; (2) to the west, the small ponds, open drains for irrigation, and pumping-stations for the cultivated land near Nefiche; (3) to the south, near the northern bank of Lake Timsah and close to the bathing sheds, some collections of water which were formed only during the rise of the Nile.

The measures adopted were briefly as follows:—

The great marsh was intersected with deep channels which were stocked with fish, the reeds were removed, and the soil (wherever this was possible) was levelled, all depressions being filled up with sand; the smaller ponds and swampy spots were all filled in, the irrigation drains were cleared and deepened, and also stocked with fish, such as eels, mullet, and a species locally known as *chaba'r* (*Tilapia gallilea*).

Destruction of Ordinary Mosquitoes.—The works undertaken for the destruction of Anopheles also helped to bring about that of Culex and Stegomyia outside the town, but those inside the dwellings had yet to be dealt with. This task did not offer any great difficulty, as it consisted in the periodical emptying of all receptacles for water, wherever this was possible, or of spreading petroleum on the water if the receptacles could not be emptied.

The town of Ismailia was therefore divided into six districts (one for each week-day), and every house was inspected once a week, and on the same day of the week, by a squad of three Arabs commanded by an European, who were told off exclusively for this purpose. During this inspection every receptacle for water, including the ornamental garden ponds, had to be emptied and dried in the presence of the chief of the squad, and the inhabitants were cautioned against immediately refilling the emptied receptacles, as this might revive the half dried up larvæ. The cesspits at the same time were treated with a mixture consisting of one part of heavy petroleum to three parts of lamp petroleum, in the proportion of one glassful to every square yard of surface. [Before commencing these petroleum operations, all the vent-holes had been covered over with metallic gauze to prevent the escape of mosquitoes, which would otherwise have been driven away by the smell of the petroleum.] The Company had also previously obtained Government sanction for the sanitary squad to enter into the Arab dwellings; but as the inhabitants were put to no expense, and had no work imposed upon them, they readily submitted to this weekly inspection, and soon volunteered their help in applying the measures adopted.

Cost. Initial Expenses.—The filling in of the ponds and drainage of the marsh land cost about £2,000 altogether.

Permanent Expenses.—The upkeep of the drains (cutting weeds and reeds, &c.) in the neighbourhood of the town costs £312 per annum; the petrolage of the cesspits and blind wells and the filling in of local puddles in the town itself costs £420 annually, or a total yearly expenditure of £732.

Results.—Since the commencement of 1903 the common *mosquitoes have disappeared from Ismailia*, and all the inhabitants have been able to dispense with their mosquito-nets, which are so troublesome and anti-hygienic in hot climates. Since the autumn of 1903 not a single Anopheles larva has been found in the protected zone, which now extends for nearly a mile all round the town.

Since 1902 malarial fevers have shown a manifest decrease, and since 1903 *no fresh case of malaria* has been notified in Ismailia.[1]

It must, however, be noted that adult Anopheles are still occasionally found in the autumn in Ismailia, probably driven in from a distance by certain winds; but that they constitute no danger is proved by the disappearance of fever from the town.

Of all the hypotheses put forward to account for the invasion of malaria in 1877, the most probable one is that Anopheles have existed from all time in this region, but that the sudden appearance of ague in 1877 was due to the arrival of malarial patients at Ismailia. At this time the Ismailieh Canal was dug, and many Italians were employed on this work, and probably several of them had already suffered from ague in their own native country.—J. E. N.

Original Communications.

BERI-BERI—A RESTATEMENT AND REPLY TO SOME CRITICISMS.

By Hamilton Wright, M.D.

Before dealing with some recent work on beri-beri and criticisms of my own views as to the nature, &c., of the disease, it may be well to restate in epitome what the latter are. This will save reference to brochures which may not be readily available.

Clinical Aspects.

After several years of exhaustive etiological, clinical, and pathological researches on beri-beri, together with a review of the work of those who had preceded me in the study of the disease, the following conclusions were formulated as to its cause, onset, course, classification and termination :—

That beri-beri is, in its origin, an acute infectious disease. That it is independent of food regarded as food, or of any micro-organism whose special habitat is a foodstuff. That on the contrary, it is caused by a specific bacillus which is to be found under those general conditions which govern most specific micro-organisms. That, generally speaking, the disease begins in those enjoying good health by more or less pronounced symptoms suggestive of indigestion. That these symptoms (gastro-duodenal syndrome) consist of oppressive feelings or pain referred to the stomach, dilatation of the latter and of the duodenum, with consequent bulging of the epigastrium, vomiting and perhaps diarrhœa. That this syndrome precedes any other symptom of beri-beri by a few hours or days, and that it marks the multiplication of the specific bacillus and the elaboration of its extra-cellular neuro-toxin in the contents of the stomach and duodenum. That the gastro-duodenal syndrome is constantly and soon joined by signs of the acute poisoning of the nervous system as the result of the absorption of the specific virus into the circulation, *i.e.*, there are anæsthesia, flaccid paresis of varying extent, œdema and cardiac irritability. That this gastro-duodenal syndrome may either subside or intensify as the poisoning of the neurones proceeds. That the acute poisoning of the neurones reaches a maximum about the twentieth or thirtieth day and then begins to subside and finally disappear. That during the development and presence of the gastro-duodenal syndrome there is probably a continuous secretion of the specific toxin, and that the syndrome, together with the rapidly spreading acute poisoning of the sensoro-motor and autonomic neurones make up acute beri-beri, or beri-beri proper.

Further, that if such cases of acute beri-beri are not treated by strict rest of the acutely poisoned neurones, the symptoms of nerve poisoning do not clear up on the elimination of the causal organism and its toxin (about the third to fourth week from the onset), but resolve into more narrowly confined symptoms which then more or less rapidly change from the acute toxæmic type to a chronic degenerative type. That is, the acute flaccid palsy (to take the most obvious symptom) insensibly resolves to chronic atrophic paralysis as the result of an inertia degeneration imparted to the neurones by the specific neuro-toxin, active only in the acute stage of the disease. I pointed out that this chronic stage of the disease is not beri-beri proper, but simply a degenerative paralysis residual to the more extensive toxæmic palsy of acute beri-beri or beri-beri proper. I feel bound to be somewhat tautologic on this question, because what seemed to many to have been a plain statement has nevertheless been misconstrued by recent critics of my views. So much for the clinical aspect of beri-beri.

Pathological Aspects.

The pathology of beri-beri was studied with strict regard to the clinical signs and duration of the disease. A considerable number of new facts were elicited, and these, with the data of the older observers, were co-ordinated as logically as possible. In regard to the pathology of beri-beri the main conclusions were as follows :—

That nearly all cases of beri-beri, fatal in the acute stage of the disease (first to sixth week), exhibit a necrosis of the gastro-duodenal and neighbouring mucosa along with the signs of inflammation. That in association with this gastro-duodenitis there was found a rod-shaped bacillus of constant morphological character. That, taken with the onset of the disease by a gastro-duodenal syndrome, it seemed pretty conclusive that the gastro-duodenitis would have to be regarded as the primary lesion of the disease, and that the constant presence of the rod-shaped bacillus was suggestive at least that we were dealing with a specific organism. Further, that the morbid anatomy of the acute stage of the disease was distinctly different from that of what I termed the residual stage. That in the former classes of cases the lesions were of the nature of an acute poisoning of the peripheral terminations of the neurones (no signs of degeneration in them) and that the changes in all other organs were secondary to such an acute poisoning. That is, there is dilatation of the right heart (no hypertrophy whatever), a small amount of fatty degeneration only, and more or less passive congestion of lungs, spleen, liver and kidneys (no necrosis in these organs at all). On the other hand, that in cases of residual paralysis (from three months' to several years' standing) there is not found a gastro-duodenitis except in cases reinfected. That the peripheral terminations of the involved neurones now show various degrees of true inertia degeneration, Wallerian in appearance, and that this degeneration has migrated towards the trophic centres. That there are found some signs of chronic derangement in the body organs, namely, dilatation of the chambers and true hypertrophy of the cardiac muscle, coextensive with the amount of degeneration in the cardiac nervous system, and the time which has elapsed since the degeneration set in ; chronic emphysema and even slight fibrosis of the lungs, with signs in the liver, kidneys and spleen of the effects of prolonged passive congestion.

Classification of Beri-beri.

Upon both clinical and pathological data there was propounded a new classification of beri-beri which I hoped would be regarded as scientific rather than merely descriptive. The older classifications took note

of some one feature of the disease, such as œdema, or muscular atrophy, and the disease was then written of as wet or dry beri-beri. There follows the new classification :—

Acute pernicious beri-beri, which is rapidly fatal because of the impact of the specific toxin on the terminations of the entire cardiac nervous system. In this class of cases there may, of course, be other signs of the acute disease: varying degrees of œdema, flaccid palsy, vaso-motor disturbance, &c. But the main features are that the onset is sudden, the cardiac neurones bear the brunt of the poison, and the cases are rapidly fatal.

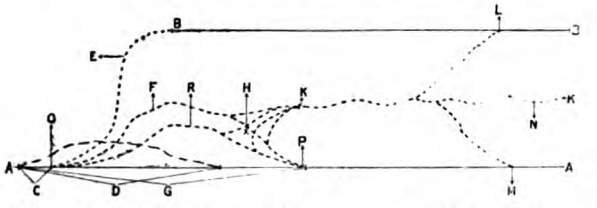
Acute and subacute beri-beri, in which the onset is more or less sudden and well marked, but in which, though there are many signs of neuronal poisoning, the virus is not specially incident on the cardiac nervous system.

Beri-beric residual paralysis, or the chronic stage of the disease due to an inertia degeneration of various kinds of neurones, from the impact of the virus in the acute stage of the disease.

These different class names, it was suggested, may be modified so as to indicate which particular neuronal system is involved, thus :—

Acute	cardiac, motor, sensoro-motor, or vaso-motor	beri-beri.
Beri-beric residual	cardiac, motor, sensoro-motor, or vaso-motor	paralysis.

Chronic beri-beri as a classifying term for cases of residual paralysis was avoided, because it implies that the causal agent is still at work. Post-beri-beric paralysis was avoided, because it implies that the atrophic paralysis of the disease followed some morbid constitutional state, minus paralysis. I have drawn attention to some striking analogies between beri-beri, as I conceive it, and diphtheria, principally that beri-beri as diphtheria appears to be due to a bacillus which multiplies locally in the vicinity or actually in a mucous surface, and produces its remote effects on the nervous system (constant in beri-beri, casual in diphtheria, however) through the agency of an extracellular neuro-toxin. Some commentators on my views, forgetting that there is no exact analogy in Nature, have, nevertheless, converted my analogy into an exact parallel. In doing so they accuse me of stating that beri-beric paralysis is always post. Above I have restated my position in this matter, I hope clearly and beyond further misconception. Perhaps the following graphic illustrations will make more clear this conception of beri-beri :—



KEY.— AA, Health line; BB, death line; C, prodromal stage of more or less marked gastro-duodenal symptoms; D, more or less well-marked gastro-duodenal syndrome, suggesting multiplication, of specific bacillus, elaboration of its toxin and absorption of it into blood stream, with consequent poisoning of neuronal terminations; O, first evidence of neuronal poisoning developing suddenly into acute pernicious beri-beri (E), which ends rapidly in death at (B), into acute and subacute beri-beri (F and R), which end in recovery at (P); G, combined gastro-duodenal and acute neuronal symptoms making up beri-beri proper, or the acute disease; H, more or less rapid passing of the acute poisoning of the neurones into an inertia degeneration, which occurs in a large number of cases, thus constituting (KK), beri-beric residual paralysis; L, termination of the residual paralysis in death from cardiac exhaustion or some intercurrent affection; M, termination of residual paralysis in recovery; N, continuation of the residual paralysis indefinitely.

Above I have spoken of this theory, pathology, and classification of beri-beri as generally applicable. Does it, however, apply to those cases of beri-beri which follow parturition, surgical and other wounds, and which occur in children at the breast of mothers suffering from the acute disease. I have already answered this question elsewhere, but it may be restated. If the central fact of the theory is considered, namely, that beri-beri is caused by a specific bacillus locally confined, which produces its remote effects on the nervous system by means of an extracellular diffusible neuro-toxin, it will be clear that such an organism may act in a wound as well as in a mucous surface. Further, that acting in a parturition wound enough toxin may be absorbed not only to cause the acute disease in a mother, but also in her nursing child by secondary absorption. It might be urged that the experimental translation of human beri-beric blood to monkeys does not produce signs of beri-beri in them. But obviously it is one thing to translate a small quantity of blood from a human beri-beric to a monkey, and another, the almost constant translation of the beri-beric virus which would take place between an infected mother and her suckling infant. In the latter case the virus would be constantly reinforcing that previously absorbed, while in the former the small quantity of virus contained in the amount of blood that could be translated would be quickly diluted and neutralised.

The data on which all of these conclusions were based were published several years ago. Naturally it has taken time for other workers to confirm them *in toto* or in detail, or to deny them. Observations have, however, recently accumulated rapidly, and it is now proposed to examine them and see if they seriously impair my own and the reasoning founded on them.

Replies to Criticisms.

Before proceeding, some ground must be cleared by reference to certain misstatements made by Dr. H. E. Durham in the *Journal of Hygiene*.

That author, by obviously personal strictures, attempted to cast doubt on the validity of certain special observations which I had made in the Federated Malay States. I have not before taken notice of his remarks, for it seemed to many that he was quite unfair. Perhaps if I state that Durham worked in my laboratory for nearly a year after my views on beri-beri had been submitted, and that on publishing what purported to be his own observations he failed to acknowledge the fact, and that, as is well-known to

those competent to discuss beri-beri, he, by his actions in the Federated Malay States, put himself out of court as a possible critic of beri-beri work done there, the matter may be brought to rest. I should not essay even this defence of my work against Durham's attacks were it not for the fact that some fair-minded critics have echoed him.

To turn now to more serious subjects. There has been considerable negative criticism of my conclusions as restated above.

Dangerfield's extensive brochure on beri-beri, published in Paris, 1905, is on the whole a negative comment on my views, inasmuch as he has submitted data on which he affirms that beri-beri is essentially a bacteræmia. He puts forward a micrococcus as the form of organism that exists in the blood stream and causes the disease. In 1900-1901 I made fairly exhaustive research of the blood of all classes of beriberics, and failed to find an organism in the flowing blood. Dr. C. W. Daniels ("Observations in the Federated Malay States on Beri-beri," London, 1906) has more recently made a similar research which was wholly negative. I shall shortly record an even later examination of the peripheral blood of acute beriberics by Wise, in which no organism of any kind was found. Finally, Drs. Hunter and Koch ("A Research into the Etiology of Beri-Beri," Hong Kong, 1906) have published a very thorough observation of the blood of beri-berics, and have made inoculation experiments which show conclusively that beri-beri is not a bacteræmia. On the whole, Dangerfield's conclusion, and with it his negative evidence against my view that beri-beri is originally an acute toxæmia, beginning in a local primary lesion, cannot be accepted.

Dr. C. W. Daniels has put forward some negative criticism of my view of the nature of beri-beri. Unfortunately it is founded on an entirely erroneous conception of both my working theory and classification of the disease. Daniels credits me as follows: "Dr. Hamilton Wright goes so far as to propose the limitation of the term beri-beri to the intestinal condition, and to describe what is at present known as beri-beri as post-beri-beric neuritis."

I have not, of course, proposed any such limitation of the term beri-beri, nor have I ever used the wholly misleading term, post-beri-beric neuritis. It is not necessary to repeat what I have restated above on this side of the beri-beri question. Having mistaken my words, Daniels would controvert my views as to the nature of beri-beri by evidence which, properly interpreted, seems to me to only support the latter. For instance, he states: "In cases admitted with beriberi, loss of appetite is common, and vomiting occasionally does occur; while distension of the epigastrium is quite a feature in the diagnosis. As these cases have quite other definite symptoms of the disease, and had usually been ill for several days, the symptoms were during the early stages of ordinary beri-beri and not during a prodromal stage."

I have never claimed more for the early, acute stage of beri beri. Had Daniels read me clearly, he would have seen that the gastro-duodenal symptoms of his cases were part of what I have termed acute beri-beri. Had he seen his cases early enough he would probably have found, as others as well as myself have pretty constantly found, that the gastro-duodenal symptoms were prodromal, as well as an accompaniment of acute beri-beri. His conclusions on this important point would then no doubt have chimed with mine, that beri-beri onsets with a gastro-duodenal syndrome, indicating the probable site of action of the specific cause.

In a further criticism of my view as to the primary lesion of beri-beri, Daniels submits a singular pathological conception. He states that the lesion of the gastro-duodenal mucosa in acute beri-beri, which he appears to have found pretty constant, is "not of an inflammatory nature such as we should expect to find in a primary lesion, but such as occur as secondary lesions, hæmorrhages, and congestions."

This view is not borne out by any published evidence that Daniels made an acceptable examination of the gastro-duodenal mucosa of acute or other beriberics. He appears to have autopsied thirty-four cases of beri-beri, thirteen of which exhibited ecchymoses and congestions of the gastro-duodenal mucosa ("The Diseases of British Malaya," Studies from Institute Medical Research, F.M.S., vol. iii., part 1). He does not claim to have been informed on the clinical histories of these cases, and there is no detailed statement of the microscopical appearances of their gastro-duodenal mucosa. I maintain that one may be grossly misled by the mere macroscopical observation of any morbid organ, and that no one is competent to generalise on such data. I may be wrong, but I am nevertheless forced to conclude that Daniels' criticism, as just quoted, is based on what he has read into my very detailed description of the macroscopical and microscopical state of the gastro-duodenal mucosa of many cases of acute beri-beri whose clinical history was known and given.

I hoped that I had made it perfectly clear that the chief lesion in the gastro-duodenal mucosa of acute beri-berics is a necrosis. There is, besides, more or less precipitation of fibrin, some small-celled and polynuclear leucocytic invasion, and spots and rings of brilliant congestion due to dilatation of capillary terminations. Actual hæmorrhages are rare, and just as rarely there may be extensive hæmorrhagic erosions. Mucosal erosions may, however, be common. Ulceration I have not seen.

According to the singular pathological conception enunciated by Daniels, this lesion in acute beri-beri, and the essentially necrotic lesions of diphtheria, cholera and tetanus, cannot be primary. It does not appear to me that Daniels' conclusion on this point can be accepted.

Daniels and others would attribute what I regard as the primary lesion of beri-beri to the action of a virus on the vagal terminations in the gut, without attempting to account for the early selective action of the poison. By similar reasoning, did we not know better, we might account for the primary lesion of diptheria as due to the action of a virus on the neuronal terminations in the palate, pharynx and larynx. It appears to me to be better pathology to reason that, given a constant primary lesion caused by a neurotoxin-producing bacillus, it will be the neuronal terminations distributed to the site of the primary lesion

which will in time first succumb to the effects of the toxin.

The rest of Daniels' views as to the etiology, &c., of beri-beri are almost purely speculative, and so do not call for reply. He does not appear to have been able to watch the disease develop in healthy subjects, and his limited observations on morbid anatomy do not seem to have been made with a knowledge of the clinical history of his cases. He, however, arrives at an important general conclusion after examination of ground which I had thoroughly explored, namely, that "beri-beri is an infectious disease. As a rule a short period of incubation and a period of exposure of less than three months is requisite for full development of the disease where the 'endemic index' is high."

It will shortly appear that this general conclusion to which I was forced, to which Daniels has been forced after an examination of much data collected by others, and to which observers like Scheube adhere, is denied *in toto* by Hunter and Koch.

Drs. Hunter and Koch's Researches.

The most ambitious recent attempt to add to our knowledge of beri-beri is that made by the just referred to authors, Drs. Hunter and Koch, in "A Research into the Etiology of Beri-beri," Hong Kong, 1906.

These observers have canvassed the whole issue as laid down in my own investigations of the disease. It will be well to continue this line in my reply to their criticisms.

First in regard to the question of etiology. The above authors attempt to show that beri-beri is not an acute infectious disease. The first facts submitted are in a description of "An Outbreak of Beri-beri in the Po Leung Kuk." A mild form of the disease was not brought under control by "thorough and complete disinfection of the buildings. This was carefully done by the staff of the Sanitary Board, and the walls were completely lime-washed thereafter, and the floors scrubbed with a solution of strong carbolic acid." Because these sanitary measures were ineffective, Hunter and Koch conclude that beri-beri is not infectious in nature. Of course, so sweeping a conclusion is not warranted by the facts of the case. The observers do not appear to have disinfected the clothes or bedding of the inmates. They make no mention of having corrected the personal hygiene of the latter, an important matter when there was, as in this instance, an overcrowding of Orientals. The food supply does not appear to have been examined for *materies morbi*, and during the continuance of the outbreak no effort was made to prevent new arrivals from introducing new infection from some endemic focus outside the Po Leung Kuk.

In all observations made in the Kuala Lumpur gaol, which Hunter and Koch would refute, the circumstances just enumerated were carefully looked to. The Kuala Lumpur observations extended over a period of more than two years altogether. The focus of infection (granting infection for the time being) was by a process of rigid exclusion narrowed to the cells of the gaol, and finally to certain of these cells almost alone. It will be clear, therefore, that Hunter and Koch's observation in this instance was inadequate to exclude beri-beri from the category of infectious diseases.

To clinch what Hunter and Koch regarded as a capital fact against the infectious nature of beri-beri, they proceeded to repeat my observation that monkeys may contract beri-beri when placed in a focus of the disease.

"Description of the Experiment A, 1-11-111. The rooms of the Po Leung Kuk, in which the majority of cases of beri-beri had occurred, were reserved for this test. The rooms were left in exactly the same condition as when they were used by the inmates of the Po Leung Kuk. Two monkeys were placed in each room, and in order to facilitate the onset of the disease the windows of the rooms were kept shut, and the light excluded as far as possible."

The monkeys, after a prolonged incarceration, did not develop beri-beri. Hunter and Koch, therefore, conclude that "The incarceration for months of monkeys in rooms presumably infected with the so-called beri-beri virus failed to induce the occurrence of the disease in them. We were unable to confirm the results of Hamilton Wright."

It must be plain to even the most casual reader that this attempt to work along the lines of my monkey experiment was a failure. The conditions of Hunter and Koch's experiment were almost indefinitely wide of the conditions under which my own observation was carried out in the Kuala Lumpur Gaol. As shown above, Hunter and Koch had by no means proved that it was the living-rooms of the Po Leung Kuk (in which they confined their monkeys) which contained the virus of beri-beri, as had been proved in regard to the cells of the Kuala Lumpur Gaol. Further, they were dealing with an institution in which only the mildest type of beri-beri had been observed, while the Kuala Lumpur Gaol had for years been a veritable hotbed of the most severe type of the disease. For instance, in ten or twelve of the Kuala Lumpur cells there was placed as many healthy Chinamen who had been roving the country as gang robbers. These men never left the cells from the time of incarceration until they contracted beri-beri. Inside a month eight of the Chinamen contracted a most severe type of acute beri-beri, while one of them died of the acute pernicious form. Again, Hunter and Koch incarcerated their monkeys in rooms with a floor space ranging from 401 to 902 square feet. The cells of the very lethal Kuala Lumpur Gaol, in which my observation was made, had a floor space of about 50 square feet. This alone was a great difference in the conditions of the two experiments, even granting that Hunter and Koch had proved by exclusion that the rooms of the Po Leung Kuk were infected. All facts considered, it does not appear that Hunter and Koch's observation on monkeys was well planned, or that it was adequate to exclude any part of my own. It certainly does not exclude beri-beri from the category of the acute infections.

Under the heading of "Feeding Experiments, B, 1-111," these observers make the following statement, and then, on the contained reasoning, proceed with certain experiments: "As certain observers, as Pekelharing and Winkler, Gerrard and others, claim to have found micrococci, &c., in the blood stream of beri-beri patients, feeding animals with the blood of such cases seemed to afford the best opportunity

for a successful mode of conveyance of beri-beri from man to animal. By this method the organisms said to be present in the blood would reach that part of the gut, namely, the gastro-duodenal mucosa, alleged to be the site of primary beri-beri infection, and in susceptible animals set up the disease. It seemed to us that, by resorting to such experiments, the question as to the presence of a definite primary lesion in beri-beri, and our hopes of obtaining positive evidence of the transmission of the disease to monkeys by this method were strengthened by the publication of Wright dealing with natural infection in monkeys incarcerated in presumably infected prison cells."

The reasoning of this paragraph does not appear sound to me. In effect, Hunter and Koch state that A. has a theory that beri-beri is caused by a bacillus which never extends into the blood stream, but acts locally in a mucous membrane, and produces its remote effects by means of an absorbable toxin; that is, the disease is a toxæmia. B., on the contrary, has a theory that beri-beri is caused by a micrococcus which gains the blood stream through the skin; that is, the disease is a bacteræmia. C., however (Hunter and Koch), propose to prove that A. is wrong in regard to his locally acting bacillus by feeding animals with blood supposed to contain the skin-piercing micrococcus of B.

Comment on such reasoning is needless, and Hunter and Koch's "Feeding Experiments, B, 1-111," based on it, do not call for attention.

Hunter and Koch now proceed along more rational lines and attempt to show that animals fed with gastro-duodenal mucosa of fatal acute beri-berics fail to exhibit signs of the disease.

Their feeding experiments, E, 1-11-111, were made on monkeys by feeding one animal in each experiment with *one bolus* composed of boiled rice and broken-down gastro-duodenal mucosa. No signs of beri-beri followed after feeding with *one bolus*. Yet the authors conclude that the experiment was negative, so far as my view is concerned that beri-beri has as its primary lesion a gastro-duodenitis. The experiment was well conceived, but nevertheless wholly inadequate as the basis of any conclusion, in regard to beri-beri. The experimenters should have borne in mind the feeding experiments made with Koch's comma.

A further attempt was made by Hunter and Koch to induce beri-beri in animals by feeding them with spleen pulp, broken-down liver, medulla, cord, brain blood, &c., of beri-berics (feeding experiments, B, 11, pigs I. to VI. and one sheep). The amount of such materials that could be given to animals was small, of course, and the boluses were seldom or never repeated. No signs of beri-beri appeared. Therefore, conclude the authors, beri-beri may not be contracted through the gastro-duodenal mucosa. So far as I know the organs with which these animals were fed have never been claimed by me to contain the bacillus of beri-beri I have always maintained that the bacillus does not extend within the body. It must be plain, therefore, that this attempt to induce beri-beri was illogical, and that no fair deductions can be based on it.

It is gratifying to turn from Hunter and Koch's illogical feeding experiments to some of their really valuable inoculation work. After a repetition of observations made by the writer several years ago, more recently by Daniels, and still later, as I shall show elsewhere, by Wise, that in no stage of beri-beri is there a bacteræmia, Hunter and Koch conclude as follows: "The repeated sterile result after inoculating bouillon and agar tubes with appreciable quantities of freshly flowing (beri-beri) blood, demonstrates more or less clearly the non-bacteræmic nature of beri-beri." This does not, of course, prove that beri-beri is not an acute infection. It simply proves that it is not of the bacteræmic type of infection.

The authors clinch this observation by a failure to induce beri-beri in monkeys, sheep, calves, rabbits, &c., by inoculating them with beri-beri blood and vaccinating them with rubbed up beri-beric organs. But these experiments do not exclude beri-beri from the category of the acute infections. They only prove that beri-beri is not a bacteræmia. They have only a remote relation to my own view that beri-beri is an acute toxæmia. On this view the remote effects of the locally acting bacillus are induced by an absorbable toxin which circulates in the blood. Hunter and Koch might have hoped to induce some signs of beri-beri in their animals by carrying over in blood from beri-berics an efficient quantity of the circulating toxin. The small amounts of blood they were forced to use, however, would put out of consideration any attempt of this kind.

Where, as the result of their experimental observations, Hunter and Koch conclude that by culture no organisms are to be found in the blood stream of beri-berics they are correct and corroborate older observations of the same order. They are also correct when they conclude that beri-beri cannot be induced by the translation of beri-beri blood to lower animals, provided that they hold to the idea of a bacteræmia as the cause of beri-beri. When, however, on such data they conclude that beri-beri is not a toxæmia caused by a locally acting organism, they go astray. They do not appear to distinguish between the idea of a bacteriæmia and a toxæmia, or so it would appear from the above quotation from their work. They appear to have forgotten, too, that any quantity of a toxin which they might translate from the human to a lower animal would be quickly diluted and probably neutralised by the body juices of the latter. It is quite a different matter in the case of a child suckling a beriberic mother, as mentioned above.

I do not think that any one will, after a careful reading of Hunter and Koch's experiments, and the reasoning on which they were largely founded, conclude with them as follows: "These experimental researches, negative though they be, possess, in our opinion, great value, as they practically prove (how may a negative experiment practically prove?), in opposition to H. Wright and others, that in beri-beri we are not dealing with an infectious disease, but one with an entirely different etiology."

Turning now from Hunter and Koch's etiological to their clinical observations, it would appear that the latter were confined to the inextensive subacute outbreak in the Po Leung Kuk. Even in this experience of the disease we are not furnished with the particulars of individual cases. Only very wide

generalisations are made. There seems to have been no attempt made to study the disease under that prime condition, rest or comparative rest, which is demanded by the nature of the affection. The patients wandered at will. It is an axiom that the true features of an acute neuritis are obscured by adding to the original symptoms others due to use of the damaged neurones. I have shown that in onset, course, and termination beri-beri presents clinically many features of an acute infection. Hunter and Koch's clinical observations do not help us to form an opinion one way or the other on this question.

In regard to the pathology of beri-beri Hunter and Koch state: "The descriptions recently given by Hamilton Wright, Mott, and others are sufficiently extensive and minute to gratify even the most curious of pathologists."

Why, then, did they not accept that pathology and its classification into the acute and residual categories, a pathology which, so far as my own work was concerned, was based on not only extensive *post-mortem* examinations, but also on a thorough study of the cases before death. My attempt was to put the morbid anatomy of beri-beri on a scientific basis, to co-ordinate the appearance of an organ or set of neurones with the symptoms expressed by them during life. For years beri-beri cadavers had been conscientiously studied by Malcommsen, Scheube, Baelz, Ellis, and others; the only fault in their observation was that the lesions found were not brought into relation with the clinical signs at the time of death. Statements were made in regard to the heart, muscles, &c., that appeared to be positive for any stage of the disease. The literature was full of such general conclusions as that there is always cardiac enlargement in beri-beri; that the somatic muscles are greatly atrophied, &c. My own efforts showed conclusively that the pathologic lesion of beri-beri varied with the stage of the disease, and that the lesion of the acute stage of the disease was an entirely different affair from that of the residual stage of the disease (*vide supra* for an outline).

It appears to me that after the frank admission of Hunter and Koch that pathological curiosity had been satisfied, they should have refrained from tabulating their morbid anatomy without any relation to the clinical histories of their cases. They state: "It is to be regretted that in the majority of cases—cadavers—examined a history of illness was not ascertainable. This was due to the fact that most of the bodies sent for section were found in the streets, in deserted houses, or on the hillsides." Only vague generalisations may be made from morbid anatomy obtained under such conditions. And so we find that Hunter and Koch have given us the pathology of beri-beri as it may be found in any old text-book article on the disease. It cannot be accepted on their clinical or *post-mortem* work any more than on their etiological observations that beri-beri is not an infectious disease.

There is but one other point in Hunter and Koch's work that should be attended to. Writing on the classification of beri-beri, they remark that beri-beri exists in two forms: "the dropsical, moist or wet form, and the atrophic or dry form. Beri-beric residual paralysis is a term which has been used in an analogous manner, and with a similar meaning to diphtheritic paralysis. The pathology of the diseases being different, the comparison does not hold, and any attempt to introduce new varieties, names, &c., is to be deprecated."

Of course the disease does not present itself in two varieties. It presents itself in a multiplicity of varieties, depending upon the extent to which the different kinds of neurones are poisoned in the acute form, and the degrees of inertia degeneration which develop in them if they do not recover on the elimination of the virus of the disease. The terms wet and dry were tentatively used over fifty years ago, before the pathology of beri-beri could be satisfactorily studied. For Hunter and Koch to continue to use them is to confuse the subject, just as they confuse it by stating that the morbid anatomy is so and so without any relation to the clinical facts and stage of the disease. Further, the term beri-beric residual paralysis was not proposed on the assumption stated by Hunter and Koch. It was proposed for the exactly opposite reasons. It ought to prevent any one confusing the residual paralysis of beri-beri which follows a previous acute palsy with the post-paralysis of diphtheria which is not post to a previous different sort of paralysis, but to certain local and constitutional symptoms which make up the disease. The classification which was proposed for beri-beri (*vide supra*) was based on clinical and pathological data studied in close relation to one another. Hunter and Koch may regard it obliquely; yet they testify to its soundness by constantly using it in their description of experimental work, and in the one clear statement they make on the pathology of beri-beri.

Taking all of the above criticisms into consideration, they cannot be said to weaken the views which I have expressed (be they right or wrong) as to the nature, cause, course and termination of beri-beri.

MALIGNANT ANTHRAX ŒDEMA IN CENTRAL AFRICA.

By A. Yale Massey, B.A., M.D., C.M.(Tor.).

Medical Officer, Tanganyika Concessions, Ltd.

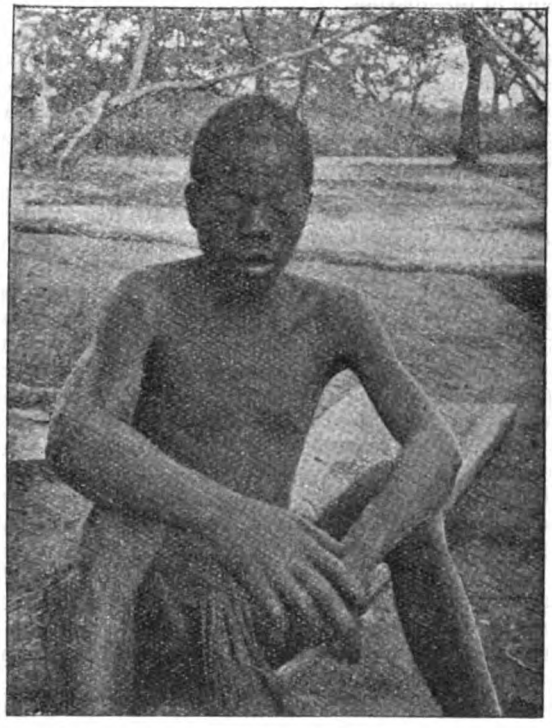
On March 14th, 1906, a black, aged 18, employed on the shed gold, carrying dirt in a bark basket, appeared at the hospital complaining of pain in his neck and shoulder. Examination revealed a slight general swelling above the right clavicle, and a very considerable swelling and œdema of the adjoining shoulder extending almost to the elbow. There was no abrasion of the skin. Temperature, 103° F. The patient did not appear to be very ill, his main trouble being that he could not use his right arm. During the next two days œdema increased and extended to the fingers which became very tense. The temperature fell to 101° F. 18th: The patient, instead of coming for treatment, went hunting mushrooms for food, saying he was all right. 19th: Proptosis of right eye and swelling of right face. 20th: Convulsions general, resembling epilepsy every couple of hours; breathing heavy; temperature normal. 21st: Proptosis marked in both eyes; left breast slightly swollen. 22nd: Unable to close the eyes completely; corneæ dry and anæsthetic; œdema of arm and hand slightly

reduced. Convulsions very frequent and always on being disturbed. No evidence of disease in the lungs. 23rd: Death.

Autopsy. — Decomposition was rapid. Serous cavities contained small amounts of fluid. Marked œdema of right arm, shoulder and neck. Spleen not enlarged. Deep glands of the right side of the neck much engorged.

Diagnosis.—The anthrax bacillus was not found in the blood before death, after more or less careful search. Fluid from the engorged cervical glands, after death, showed numerous anthrax bacilli, and mice inoculated with this fluid died in five days, their blood showing innumerable bacilli of anthrax.

Treatment. — Symptomatic with good feeding, stimulants and quinine. It is regretted that a supply



Photograph taken on March 21st, or eighth day of disease.

of Sclavo's anti-anthrax serum,[1] which has been used with such marked success in England and on the Continent, was not available.

Conclusions.—This is the first case of anthrax that I have diagnosed in a six years' practice in Central Africa. It is quite possible that some sudden deaths of unknown cause among natives may have been due to the *Bacillus anthracis*. That there should be marked external œdema without the pustule seems to be contrary to the rule. Infection may have been through the mucous membranes of the nasal fossæ, the mouth or the pharynx, to the deep cervical glands.

A noticeable feature was that the patient never took his illness seriously, and even when in a critical condition did not appear to feel very ill.

Business Notices.

1.—The address of the JOURNAL OF TROPICAL MEDICINE is Messrs. BALE, SONS & DANIELSSON, Ltd., 83-91, Great Titchfield Street, London, W.

2.—All **literary communications** should be addressed **to the Editors.**

3.—All **business communications** and **payments,** either for subscriptions or advertisements, should be sent **to the Publishers** of the JOURNAL OF TROPICAL MEDICINE. Cheques to be crossed The Union Bank of London, Ltd.

4.—The Subscription, which is **Eighteen Shillings** per annum, may commence at any time, and is payable in advance.

5.—Change of address should be promptly notified.

6.—Non-receipt of copies of the Journal should be notified to the Publishers.

7.—The Journal wil be issued on the first and fifteenth day of every month.

Reprints.

Contributors of Original Articles will be supplied FREE with six copies of the Journal if a request accompany the MS. If reprints are required they will be supplied by the publishers, if the order is given with remittance when sending the MS. The price will be as below:—

50	Copies of four pages,		5/-;
100	,,	,,	6/-;
200	,,	,,	7/6;
50	Copies beyond four up to eight pages,		8/6;
100	,,	,,	11/-;
200	,,	,,	14/6.

One page of the Journal equals 3 pp. of the reprint.

If a printed cover is desired the extra cost will be for 50 Copies, 5/6; 100 Copies, 6/6; 200 Copies, 7/6.

THE

Journal of Tropical Medicine

AUGUST 15, 1906.

THE SIVEWRIGHT PRIZE.

THE prize given by Sir James Sivewright, K.C.M.G., M.A., LL.D., has been awarded to John D. Gimlette, M.R.C.S., L.R.C.P., of the Malay Native States, for his contribution entitled "The Puru of the Malay Peninsula," published in the JOURNAL OF TROPICAL MEDICINE on May 15th and June 1st, 1906.

THE BELILIOS PRIZE.

THE prize given by Raphael Belilios, Esq., has been awarded to Joseph Herbert Ford, B.S., A.M., M.D. (Captain, Assistant Surgeon, U.S. Army; Professor of Diseases of the Tropics in the Medical Department, Columbian University, Washington, D.C.), for his contribution entitled "The Treatment of Dysentery," published in the JOURNAL OF TROPICAL MEDICINE, July 15th, 1904, and to J. G. Berne, Captain, R.A.M.C., for his contribution entitled "The Treatment of Dysentery," published in the JOURNAL OF TROPICAL MEDICINE, August 1st, 1904.

THE ETIOLOGY OF BERI-BERI.

THE categorical reply of Dr. Hamilton Wright to critics of his well-known theory as to the nature, cause, course and termination of beri-beri, is interesting reading. That it will carry conviction to unbelievers is another matter; but all will agree that his formulated conceptions bear a scientific impress which cannot be passed over slightingly or without careful consideration. Drs. Hunter and Koch, of Hong Kong, have given the matter their earnest attention, and that they have approached the subject in a truly scientific spirit is abundantly apparent from the detailed criticism of their published report which Dr. Hamilton Wright has found it necessary to bestow upon their work.

Hamilton Wright's contention is well set forth in the article we publish to-day, and we refer our readers to the opening paragraphs of his contribution for a further enunciation of his views. Shortly, it may be stated, that according to Dr. Hamilton Wright beri-beri is, in its origin, an acute infectious disease. It is caused by a specific bacillus having its habitat in the gastro-duodenal tract; the bacillus induces a necrosis of the mucosa of that part of the alimentary canal and "a toxin is developed, and the syndrome, together with the rapidly spreading acute poisoning of the sensoro-motor and autonomic neurones, make up acute beri-beri, or beri-beri proper." This is a clear, definite and logical position, and only requires for its establishment clinical and pathologic confirmation. This confirmation Dr. Wright maintains that he has established, and his opinion is shared by not a few.

Drs. Hunter and Koch tested Dr. Hamilton Wright's views on beri-beri by extensive pathological and bacteriological investigations, and their conclusions are:—

(1) There is no evidence that beri-beri is an acute specific infectious disease.

(2) No micro-organism, of the hitherto described forms, has been found in any organ or tissue of a beri-beri patient or cadaver which could be brought into causal relationship with the disease.

(3) Experimentally it has been found impossible, by any method, to call forth the disease in any animal.

(4) In our experience true beri-beri does not exist in monkeys infected either naturally or experimentally.

(5) Beri-beri, as the result of our investigations, would appear to be non-micro-organismal in nature. We are inclined to bring some chemical poison into causal relationship with the disease.

(6) Our results are in direct opposition to those obtained by Dr. Hamilton Wright.

How the conclusions are answered and dealt with by Dr. Hamilton Wright will be found in his article published in the current issue.

That beri-beri is a serious malady in Hong Kong there can be no doubt, for Dr. J. C. Thomson, who is in charge of the Tung Wah Hospital, Hong Kong, states that "Beri-beri is a most deadly disease, and is now (1905 report) alarmingly prevalent in the colony."

A STUDY OF THE CAUSE OF SUDDEN DEATH FOLLOWING THE INJECTION OF HORSE SERUM. By Milton J. Rosenau and John F. Anderson, Hygienic Laboratory, United States Public Health and Marine-Hospital Service.

In their introduction to this enquiry the authors state that: "It has long been known that the blood of certain animals is poisonous when transfused or injected into certain other species.

"Many instances might be cited showing that the blood serum of one animal has poisonous properties when injected into an animal of another species. But the blood serum of the horse apparently lacks such poisonous action. Very large quantities of the blood serum of the horse may be injected into man, rabbits, guinea pigs, and many other animals without serious inconvenience, except occasionally a slight reaction at the site of inoculation.

"In a certain proportion of cases the injection of horse serum into man is followed by urticarial eruptions, joint pains, fever, swelling of the lymph nodes, œdema, and albuminuria. This reaction, which appears after an incubation period of eight to thirteen days, has been termed by Pirquet and Schick the 'serum disease.'

"In exceptional instances sudden death has followed an injection of horse serum in man.

"These studies were taken up in October, 1905, in order to throw light upon the cause of this unfortunate accident. We have shown that ordinarily horse serum is a comparatively bland and harmless substance when injected into certain animals; but these animals may be rendered so susceptible that an injection of horse serum may produce sudden death or severe symptoms. For example, large quantities of horse serum may be injected subcutaneously or into the peritoneal cavity of a guinea pig without apparently causing the animal the least inconvenience. However, if a guinea pig is injected with a small quantity, say $\frac{1}{250}$ c.c., of horse serum and after the expiration of a certain interval is again injected with the horse serum the result will probably be fatal. The first injection of horse serum has sensitised the animal in such a way as to render it very susceptible to a toxic principle in horse serum. It is probable that when the guinea pig is injected with the first, or sensitising, quantity of serum the strange proteid contained in the horse serum develops in the body of the guinea pig 'antibodies' which, when brought into contact with more horse serum given at a second injection, produce either a union or a reaction, which causes the toxic action.

"A certain time is necessary to elapse between the first and second injections of horse serum before this toxic action is able to manifest itself. This 'period of incubation' is from ten to twelve days, and corresponds suggestively with the period of incubation of the serum disease which Pirquet and Schick place at eight to thirteen days.

"Guinea pigs may be sensitised with exceedingly small quantities of horse serum. In most of our work we used quantities less than $\frac{1}{250}$ cc. and we found in one instance that $\frac{1}{1,000,000}$ cc. of horse serum was sufficient to render a guinea pig susceptible.

"It also requires very small quantities of horse

serum, when given in a second injection, to produce poisonous symptoms. One-tenth c.c. injected into the peritoneal cavity is sufficient to cause the death of a half-grown guinea pig. One-tenth c.c. of horse serum injected subcutaneously is sufficient to produce serious symptoms. The fact that this toxic action may be developed by such small quantities of serum, and the fact that exceedingly small quantities are sufficient to produce symptoms and death upon a second injection, *a priori* places both the sensitising and the toxic principle in the horse serum in the 'haptin group' of substances in the sense used by Ehrlich.

"A still further indication that the side-chain theory in its broadest sense may be applicable is the further fact that immunity may be produced against the toxic action by multiple injections of the serum.

"While at first we thought that diphtheria antitoxin had some relation to this action, we are now able to state positively that it has nothing whatever to do with the poisonous action of horse serum; further, that diphtheria antitoxin in itself is absolutely harmless. The toxic action which we have studied is caused by a principle in normal horse serum and is entirely independent of the antitoxic properties of the serum."

LONDON SCHOOL OF TROPICAL MEDICINE.

Colonel Kenneth Macleod, I.M.S., M.D., LL.D., Hon. Physician to the King, will deliver the address at the opening of the Winter Session of the London School of Tropical Medicine, on October 8th. His Grace the Duke of Marlborough, the President of the Seamen's Hospital Society, with which the School of Tropical Medicine is affiliated, will take the chair on the occasion.

His Grace has also consented to preside at the annual dinner of the staff and students on the evening of the day of the address.

21st Session—July, 1906.—*Examination Result.*

Capt. L. P. Stephen, I.M.S., M.B., Ch.B. (Aberd.), D.P.H. (Lond). With distinction.

L. A. Prins, L.M. & S. (Ceylon), L.R.C.P. & S. (Edin.), (Colonial Service). With distinction.

Capt. A. W. Cook Young, I.M.S. M.B., Ch.B., D.P.H, (Aberd.). With distinction.

Major E. Wilkinson, F.R.C.S. (Eng.), L.R.C.P., D.P.H. (Camb.). With distinction.

W. S. Allan, M.B., Ch.B. (Glas.).

R. T. Booth, M.B., B.Ch. (R.U.I.)

I. McW. Bourke, M.R.C.S., L.R.C.P. (Colonial Service).

John Cross, M.B., Ch.B. (Glas.) (Colonial Service).

B. M. Flood, L.R.C.P. & S. (Edin.) (Colonial Service).

E. N. Graham, L.R.C.P., F.R.C.S. (Edin.)

E. M. Nicholl, M.B., C.M. (Edin.)

J. Ottley, L.R.C.P. & S. (Edin.) (Staff-Surgeon R.N. retired).

E. C. Peake, M.B., Ch.B. (Edin.)

E. Robledo, M.D. (Columbia, S. America).

A. B. Tighe, M.B., B.Ch. (Dublin).

W. M. Wade, M.B., B.Ch. (Dublin).

Miss K. Wyss, M.D. (Zurich).

Abstract.

Human Trypanosomiasis. By Dr. Ayres Kopke, Professor at the Lisbon School of Tropical Medicine. Paper read before the Fifteenth International Medical Congress, Lisbon, April, 1906.

Professor Ayres Kopke here states the results of his researches as to the relative value of trypanosomes and of micro-organisms as causes of the symptoms and histo-pathological lesions peculiar to sleeping sickness.

He first continued the verification of the constant presence of trypanosomes in all cases of sleeping-sickness, and the identity of the trypanosomes, which cause the Gambia fever and sleeping sickness, and then endeavoured to ascertain whether the former disease was merely the first phase of the latter, and whether the appearance of the severe nervous symptoms was due only to the protozoon, or if the later infection by diplo-streptococci, aided by the first-named parasite, was really the determining cause of the final phase of the disease. Lastly, as the most important desideratum in so fatal a disease would be that of discovering a substance which would act on the *Trypanosoma gambiense* precisely as quinine acts on the malarial parasite, it was necessary to make therapeutic experiments on animals previously infected, on the lines of research adopted by Ehrlich, Shiga, Laveran and Wolferstan Thomas. The total number of cases observed by Kopke amounted to 56, of which 3 were not diagnosed as sleeping sickness. Of the 53 cases, trypanosomes were present in all of them; 40 were punctured in the lumbar region, and all showed trypanosomes in their cerebro-spinal fluid; 38 were clinically studied up to the time of death, and 36 were examined *post mortem*, and in all of these latter cases sections of the nervous centres showed leucocytic infiltrations round the vessels. Bacteriological researches were also made during life and after death; the cultivating media included bouillon and ascitic fluid, Kiefer's medium, Martin's bouillon, Martin's gelatine and simple gelatine.

During life only one case (and that only shortly before death) showed diplo-streptococci. After death, these streptococci were searched for in the sub-arachnoid exudation of the brain, the fluid in the ventricles, the heart's blood, and sometimes in the fluid obtained by lumbar puncture; they were found in 51·4 per cent. of the cases.

As regards treatment, up to the end of May, 1905, the patients were given cacodylate of soda, adrenalin, iodine and collargol, but without any favourable result. After this date, he prescribed trypanroth, alone or in combination with arsenite of soda or with atoxyl. Latterly he restricted himself to the use of the last-named method, as suggested by Thomas. Under this treatment, those patients who were not in an advanced stage of the disease showed great improvement (cessation of fever, less somnolence, increased muscular energy, more active nutrition), and the trypanosomes disappeared from the peripheral blood and from the ganglionic juice, although they were still present in the cerebro-spinal fluid.

The following are the conclusions arrived at :—

(1) In all the cases diagnosed as sleeping sickness the *T. gambiense* was invariably found.

(2) In the 40 cases on which lumbar puncture was performed, an examination of the cerebro-spinal fluid invariably revealed trypanosomes.

(3) In some cases, although the patients had trypanosomes in their cerebro-spinal fluid, marked nervous symptoms were not present.

(4) The search for diplo-streptococci during life, with one solitary exception, was negative, but after death 51 per cent. of the cases showed positive results in the blood and spinal fluid.

(5) None of the animals injected with the cerebro-spinal fluid showed the perivascular infiltrations in the nervous centres which are so constantly found in those patients who die from sleeping sickness.

(6) As regards the atoxyl treatment, a weekly hypodermic injection of 10 to 15 cc. of a 1 in 10 solution, constantly repeated for several months, showed a considerable improvement in the condition of the patients, but it is doubtful whether a cure can be obtained by this means alone. The number of trypanosomes is diminished in the blood and ganglionic juice, and the inoculation of animals may give a negative result; but trypanosomes still persist in the cerebro-spinal fluid, probably owing to the impermeability of the meninges to drugs, for which reason—

(7) Medicines—to be efficacious—should be simultaneously administered by hypodermic injection and by injection into the subarachnoid space immediately after lumbar puncture. Experiments are now being made with a 1 per cent. solution of lysol. J. E. N.

Reviews.

ILLUSTRATIONS OF BRITISH BLOOD-SUCKING FLIES, WITH NOTES. By Ernest Edward Austen, Assistant, Department of Zoology, British Museum (N.H.), 1906. Pp. 74, with 34 coloured plates. Printed by order of the Trustees of the British Museum, London, 1906. Price 25s.

This volume, which is obtainable at the British Museum (Natural History), Cromwell Road, London, S.W., and at several booksellers', is one of which the Museum authorities may be justly proud. The illustrations by Mr. A. J. Engel Terzi are excellent. It is impossible to speak too highly of Mr. Terzi's beautiful drawings. Scientifically correct in drawing, in proportion and in colour, the illustrations have been delineated with Mr. Terzi's usual care and exceptional skill, and a higher guarantee of their accuracy and completeness cannot been given. The text by Mr. E. E. Austen is written in an attractive manner and may be understood by one unskilled in the technicalities of biological nomenclature. The information collated in the volume is wonderfully wide, considering the few, the very few, people who do anything practically to advance this subject. To Lieut.-Col. J. W. Yerbury the Museum and Science generally is indebted for the devotion he has shown to advancing our knowledge of the Diptera, but we want many scores of persons imbued with Lieut.-Col. Yerbury's enthusiam before we can be said to have in any way perfected our knowledge of the subject. The volume before us should stimulate many men and women to take an intelligent interest in a subject which is aiding the medical profession to trace the origin, or at least the mode of transmission, of several of our most common ailments.

Correspondence.

THE TREATMENT OF "MALARIA ULCERS" BY LOCAL APPLICATIONS OF QUININE.

To the Editors of the JOURNAL OF TROPICAL MEDICINE.

SIRS,—Replying to the enquiry of "W. D. G." in the JOURNAL for April 2nd, 1906, as to the method of applying quinine to the so-called "Malaria Ulcers," I may say that the main object seems to be accomplished when the alkaloid (soluble or in solution) is brought into contact with the cleaned surface of the ulcer. Any soluble salt of quinine may be used, either dissolved in water and applied by means of a pledget of cotton wool, or dusted dry on the surface of the sore. The latter seems to be the most satisfactory procedure, for then the quinine dissolves slowly, and its effect is more prolonged. An important matter is to get the sore clean before applying the quinine, as the effect is otherwise *nil.* Salicylic acid is often useful in this preliminary cleaning up. Quinine should also be administered internally during the treatment of the sores.

A majority of our local "Malaria Ulcers" (which, by the way, have not been proven to hold any ætiological relation to malaria) will heal rapidly under treatment similar to that here described.

I remain, Sirs,
Yours, &c.,
CREIGHTON WELLMAN.

Benguella, W. Africa,
June 20th, 1906.

Obituary.

LIEUTENANT FORBES TULLOCH, R.A.M.C.

THE rapid termination of the trypanosomiasis infection in the lamentable case of this most promising young officer and investigator will come as an additional shock to all interested in tropical medicine. The duration of such cases is usually much more protracted, and though no cases of recovery can be recalled, it cannot be denied that recent therapeutic experiments on animals have been so promising that one felt entitled to retain some hope as long as life remained.

The case is a poignant illustration of the dangers that beset the investigation of diseases in general and of tropical diseases in particular, especially as it chances that only good fortune has saved another member of the Commission from a like fate. One of them, in fact, accidentally pricked himself with a capillary tube full of trypanosomes, but fortunately none of the latter can have entered the wound, as the entry of even a single parasite would presumably suffice to infect. While at Entebbe, Lieutenant Forbes Tulloch contributed to the *Transactions of the Royal Society* a valuable paper on "The Anatomy of Stomoxys," which would alone suffice to demonstrate his qualifications as a skilled investigator. The tragedy

of his death is, moreover, enhanced by the fact that the deceased officer married just before proceeding to Uganda, and hence leaves a young widow to mourn his loss. Lieutenant Forbes Tulloch received his medical education at St. Mary's Hospital, Paddington, and we cannot do better than close our notice by extracting from the pages of the Hospital *Gazette* the subjoined notice from the pen of a personal friend:—

"It is with deep regret that we note the sad death of Lieutenant Forbes Tulloch. He qualified in 1901 and went to South Africa as a Civil Surgeon, and in 1903 he obtained a commission in the Royal Army Medical Corps. Last year he went to Uganda as a member of the Commission for the investigation of Sleeping Sickness, and about four months ago he contracted this disease by wounding his hand with an infected knife. He was invalided home and was treated in the Queen Alexandra Military Hospital at Millbank, but the disease ran an unusually rapid course and he died on June 20th, at the early age of twenty-seven.

"We who remember him during his student days recall his good nature, his generosity and the geniality of his bearing, his character being such as made him ever one of the most popular of men amongst us. We remember, too, the enthusiastic way in which he worked at any subject, in which he was interested, such as micro-photography, to which he devoted much time and with conspicuous success.

"In a peculiarly sad and tragic way his life was cut short and his name added to the long and honourable list of those of our profession who have met their death at their noble calling. In him science loses a devoted servant, lost in her own service, and St. Mary's honours him for his life and for his death."

MAJOR H. W. ELPHICK, M.B., I.M.S.

We regret to have to record the death of Major H. W. Elphick, of the Indian Medical Service, at the comparatively early age of forty-one.

Major Elphick entered the service on September 30th, 1898, and arrived in India the following spring. From the first he withstood with difficulty the trying climate of the Plains of India, and he would have probably been better advised had he decided to abandon the attempt to cope with it.

His liking for India and his keen interest in the work, however, led to his disregarding repeated warnings, and struggling on where many men would have given in, it cannot be doubted that he has fallen a victim to the power of a will stronger than his frame.

Most of his service was passed in the Civil Department in the United Provinces, where he was well known and greatly liked, and his death will be deeply regretted by a large circle of friends.

For several years he was Civil Surgeon of Dehra Doon, the cooler climate of which, it was hoped, would enable him to continue his service. Unfortunately, this district is close to that powder magazine of Indian epidemics, the town of Hurdwar with its periodical religious fairs, so that the services of the Civil Surgeon of Dehra are often put into requisition during times of danger. During the desperate efforts of the authorities to guard Hurdwar from the spread of plague by wholesale disinfection, a riot took place in which Major Elphick was brutally assaulted. Though not absolutely dangerous, his injuries were so grave as to have a most serious effect on the health of a man never strong at the best of times, and there can be no doubt that the final break up of his health was due to the injuries he received. He had to take sick leave, and failing to recover, was placed on temporary half-pay on March 6th, 1905, and died at Rugby, on May 20th, 1906. His death will be felt as a personal loss by all his old colleagues in the United Provinces, for he was a man of charming personality, who never made an enemy.

THE REV. RODERICK JOHN JOHNSTONE MACDONALD, M.D.Edin.

The Rev. Roderick John Johnstone Macdonald, M.D.Edin., of the Wesleyan Methodist Missionary Society, was killed in China by pirates on the West River of the Kwangtung Province. The boat on which he was travelling was attacked by river pirates; the captain was shot, and Dr. Macdonald, who was a passenger by the boat, went to his assistance: whilst attending to the captain's wounds, Dr. Macdonald was himself fatally wounded.

After graduating at Edinburgh, M.B., C.M., in 1881, and M.D. in 1884, Dr. Macdonald went to China as a missionary, and was stationed at Wuchow, in the Kwangsi Province. The hospital under his charge not only increased in size by his indefatigable exertions, but through his tact, skill, and untiring devotion attained to widespread repute throughout the southern provinces of China. In addition to his hospital work, Dr. Macdonald officiated at Wuchow as medical officer to the Imperial Chinese Maritime Customs and as surgeon to the British Consulate and gaol. A medical missionary of Dr. Macdonald's stamp is a valuable national asset, and his loss under so tragic circumstances brings home to us the risks that missionaries run, not only from disease in unhealthy parts of the world, but from the turbulent spirits that are ever ready to raise their hand against them from one cause or another. The sympathy for his widow and two young sons is sincere and widespread.

Notes and News.

The Turkish Government contemplates building a hospital of 300 beds at Mecca. A dispensary already exists at Mecca, and it is intended to increase its scope of usefulness, and supply drugs gratuitously. Amongst other schemes for the benefit of the city and its pilgrims, an improved water supply is proposed.

Amongst the Turks, in both Europe and Asia, spring blood-letting is extensively practised.

C. T. GRAYSON, U.S.A., has brought out a mosquito net for use in hammocks, termed the Grayson-Graeme hammock mosquito net.

THERE are 120 male and 180 female medical missionaries in India.

THE cocaine habit is growing to an alarming extent amongst both Hindus and Mahomedans in Delhi. Amongst all classes of the community, rich and poor, men and women, adults and children, the habit is said to be prevalent.

INDIAN MEDICAL SERVICE.—The following were the successful candidates at the examination for admission to the Indian Medical Service held on July 24th, and four following days:—

J. Taylor, M.B.; A. D. Stewart, M.B.; C. H. Cross; R. A. Chambers, M.B.; R. H. Bott, F.R.C.S.; N. N. G. C. McVean, M.B.; J. Morison, M.B.; S. G. S. Haughton, M.B.; F. W. Cragg, M.B.; N. S. Simpson; S. Singh; R. F. Hebbert, M.B.; J. F. James, M.B.; J. Smalley, M.B.; A. S. Leslie, M.B.; C. M. Roberts, M.B.; A. P. G. Lorimer, M.B.; W. M. Thomson, M.B.; H. B. Scott; and F. C. Fraser, M.D.

SURGEON-GENERAL GUBBINS is gazetted P.M.O. in India, *vice* Sir Thomas Gallwey, K.C.M.G., C.B., appointed P.M.O., Aldershot.

LADY MINTO'S Fund for the Indian Nursing Association now amounts to Rs.25,000.

A TELEGRAM published elsewhere announces certain changes in the organisation of the Indian Medical Service. Since 1896 officers appointed to the Service have been allotted to the military area, though borne on one general list, and while liable in emergency to serve anywhere, are ordinarily employed in the areas to which they happen to be posted. In future the territorial allotment will be abolished, the three Presidency and General Lists of officers being amalgamated, but officials already in the Service will, as far as possible, be employed in the areas for which they are eligible under existing conditions. Future recruits to the Service will be liable to military employment in any part of India, but for civil employment they will be allowed, according to their position in the examination lists, to elect for service in certain specified areas, though in emergency they will be liable for service anywhere. —*Pioneer Mail*, July 20th, 1906.

INOCULATION IN RANGOON.—Since the issue of the circular last week by the Rangoon Municipality plague inoculation is being accepted here, over seven hundred persons having already submitted themselves to the operation.—Rangoon, July 12th.

AN account is given in the Indian *Pioneer* of what promises to be an important discovery in connection with plague prevention. This is the fact that the crude oil left after the distillation of petroleum is a most valuable insecticide. Hitherto, the rat flea, now believed to be the ordinary channel of infection with plague bacillus, has defied the usual disinfectants, but according to Dr. Turner's report to the Bombay Corporation it succumbs at once to treatment with crude oil. Should Dr. Turner's results be borne out by further trials really effective disinfection of houses where plague has occurred will become possible.

NURSING IN INDIA. — The Up-country Nursing Association is to be absorbed in the Indian Nursing Association, which is being organised to provide skilled nurses throughout Northern India by the Countess of Mayo, wife of the Viceroy. The scope of the amalgamated Association will furnish nurses for the United Provinces, the Punjab, Rajputana, the North West Frontier Province, Baluchistan, Central India, Eastern Bengal, Assam and Burma.

THE annual dinner of the Indian Medical Service was held on June 29th in the United Service Club, Surgeon-General Bomford presiding. There were also present: Colonel Bate; Lieut.-Colonels Bamber, Leslie and Dawson; Majors Macnamara, Gee, Macnab, Browning Smith, Seton, Heard, Birdwood, and Sutherland; Captains Cochrane, Ainsworth, Cornwall, Baird, Greig, Barron, Trafford, H. Ross, J. H. Murray, Harvey and MacGilchrist, and Lieutenant Proctor.

AN accusation of adulteration has been brought by the Hyderabad Government against its opium contractors, which is creating great local interest. Gum, black sand, and the husks of *sangizira* are, it is stated, used to increase the bulk and weight of the opium as retailed. The case has been adjourned to admit of expert analysis of the opium seized in Madras.

THE Chief Court of Rangoon has been transferred to another building for a week, on account of dead rats, which were found to be infected with plague, being discovered in the record rooms.

HYDROPHOBIA IN ASSAM.—Recently, there have been several cases of hydrophobia in Assam from dog and jackal bites. The Indian Tea Association of that province have accordingly asked the local Government to issue orders for the prompt destruction of mangy and ownerless dogs, and to consider whether the imposition of a dog tax would not help to rid the bazaars and bustis, which are now swarming with useless and dangerous animals. — *Pioneer Mail*, June 29th, 1906.

MALARIA.—A. Woldert, of Tyler, Texas, U.S.A., found, except in one instance, anopheles quadrimaculata in the houses in which autochthonous cases of malarial fever prevailed in Philadelphia and Texas. In cold, frosty weather the male anopheles increased in numbers, but the females gradually disappeared.

Geographical Distribution of Disease.

As information arrives we publish, under this heading, the principal diseases met with in tropical and sub-tropical countries, so that those interested in the Geographical Distribution of disease may have a means of gathering information concerning the prevalent ailments in different parts of the world.

Cholera.—The outbreak of cholera in the Philippines is subsiding. The use of the vaccine prepared at the Government laboratory is giving excellent results.

Malaria.—The U.S. cruiser *Columbia* had 165 out of 300 marines on board infected by malaria contracted at Panama when she sailed recently for Boston *via* Porto Rico.

PLAGUE.

Persia.—Plague continues in epidemic form in the Seistan District. The trade by the Nuski route with Eastern Persia is seriously threatened, owing to the prevalence of plague.

Australia.—In Brisbane up to June 16th the fresh cases of plague during the present outbreak, which commenced on March 10th, 1906, numbered 7, and the deaths from the disease 3. In Rockhampton, after an absence of six years, plague appeared on April 2nd, 1906; since then and up to July 7th, 1906, the fresh cases of the plague numbered 11.

Mauritius.—One case of plague reported during the week ended July 14th; the patient died. During the week ended July 26th 1 case of plague reported; the patient died. Since March 24th, 1906, Mauritius had been free from plague.

Personal Notes.

INDIAN MEDICAL SERVICES.

India Office: Arrivals of Indian Medical Officers in London.—Lieutenant-Colonel A. W. Alcock, C.I.E.; Major W. J. Buchanan.

Extensions of Leave.—Captain S. H. L. Abbott, Lieutenant-Colonel O. H. Channer, 6 m., Med. Cert.; Captain E. S. Parker, 6 m., Med. Cert.; Captain A. T. Pridham, 1 m., Med. Cert.; Lieutenant-Colonel J. Sykes, 8 d. furlough; Major T. W. Irvine, study leave, 1 m.; Major R. H. Castor, study leave, 6 w.; Major S. H. Henderson, study leave, 2½ m.; Major G. F. M. Ewens, from April 24th to June 30th, 1906; Captain F. A. Smith, study leave, February 15th to July 15th, 1906; Captain W. J. Wellock, study leave, March 1st to May 31st, 1906.

Permitted to Return to Duty.—Captain E. L. Perry, Captain W. Lapsley, Captain A. W. C. Young, Lieutenant-Colonel J. R. Adie, Lieutenant-Colonel J. Sykes, Lieutenant-Colonel J. J. Pratt, Colonel J. McCloghry.

Leave.

Honorary Captain M. Murphy, I.S.M., Civil Surgeon, Parlabgarh, privilege leave, 2 m.

Postings.

Captain T. G. N. Stokes, on special duty, Pachmarhi, to officiate as Civil Surgeon, Belaspur.

Captain J. G. P. Murray, to be 2nd Surgeon, Presidency General Hospital.

Lieutenant J. Catto, 16th Rajputs, to hold additional Civil Medical Charge of the Manipur State.

Colonel Wilkins, P.M.O., Burmah, is transferred in same capacity to Secunderabad.

LIST OF I.M.S. OFFICERS IN CIVIL EMPLOY AT PRESENT ON FURLOUGH.

NOTICE.

HENRY D. MCCULLOCH, M.B., C.M., late Chief Medical Officer Hyderbad State Railways Hospitals, Deccan, after serving twenty-one years in India, qualified further at the Liverpool School of Tropical Medicine, and has during the last two years settled in practice at "Bassendean," Bournemouth, England.

Recent and Current Literature.

A tabulated list of recent publications and articles bearing on tropical diseases is given below. To readers interested in any branch of tropical literature mentioned in these lists the Editors of the JOURNAL OF TROPICAL MEDICINE *will be pleased, when possible, to send, on application, the medical journals in which the articles appear.*

"Journ. Amer. Med. Assoc." January 2, 1906.

TAPE-WORM TREATMENT.

Ritter, John, in an article entitled "Some Parasites Infesting the Human Intestine," states that it is not necessary to fast before and after the administration of a tæniafuge for tapeworm. He advises a calomel and colocynth capsule or pill with cascara and jalap added after dinner, and on the following morning, when the bowels have been well emptied, the following emulsion:—

R.	Resinæ podophyllini	...	...	gr. i
	Oleoresini filicis maris	...	...	ʒiss
	Extracti fluidi kamalæ	...	...	ʒiii
	Spiritus chloroformi	...	...	ʒi
	Mucilago acaciæ ...	...	...	ʒi
	Aquæ menthæ piperitæ q. s. ad	...	...	ʒiii

M. Ft. emulsio. Sig.: Take in three equal doses at intervals of half an hour.

The same drugs may be given in capsules, the extract of kamala being evaporated previously to the consistence of syrup, and the oleoresin of male fern being added slightly warm.

"Therapie der Gegenwurt," Berlin, vol. xlvi., No. 12.

COOKED STARCH IN DIARRHŒA.

Hauffe, G., recommends cooked starch sipped in teaspoonfuls from time to time in diarrhœa of any kind. He finds it especially beneficial in the tubercular variety. As a gargle in sore throat it is particularly soothing.

"Hygien Rundschau," T. xvi., p. 405.

CULTURE MEDIA FOR CHOLERA VIBRIOS.

Doebert and Johannissian tested the efficiency of Hirschbruch and Schwer's medium, which is composed of gelose and Liebig's extract, to which is added some crystals of violet and heliotrope with the view of distinguishing choleraic from *B. coli* colonies; but find that the growth is greatly retarded. In both the above medium and Koch's, the colonies are fewer and smaller, and this method, therefore, fails to come up to the expectations promised for it.

"Journal of Infect. Diseases," T. iii., p. 394.

THE TRYPANSOMES OF TSETSE-FLIES.

Novy, Fred. G., endorses the views of Minchin and his colleagues to the effect that the flagellates found by Gray and Tulloch in the intestinal canal of *Glossina palpalis* have no connection with *Tryp. gambiense*. Novy had also some preparations of the intestinal contents sent him from Uganda, by Gray, and considers that the forms described by Koch as evolutionary stages of *Tryp. gambiense* and *Brucei* are entirely different from these flagellates, for the following reasons:—

(1) The Tsetse forms are much longer than the blood parasites.

(2) Their presence in flies that had no opportunity of biting infected animals, as *e.g.*, in the Tsetses of the island of Kimmi, already instanced by Minchin.

(3) The failure to obtain evolutionary forms from Trypanosomes ingested by flies fed on infected animals.

(4) The impossibility of systematically infecting animals with the flagellates of these Tsetses.

(5) The analogy of the Typanosomes of Mosquitoes.

Novy then proceeds to describe the various forms met with, the great variety of which tends to the conclusion that they belong to several distinct species. He proposes the name *Trypanosoma Grayi* for the numerous forms in one of these flies. These extremely varied forms belong to two types: one very long and thin with a long free lash, bacilliform nucleus, and large centrosome in front of the nucleus; and the other thicker and shorter, with rounded nucleus and centrosome close to it, well developed undulating membrane, and short free lash. He compares these two types with the male and female forms of Koch. It should be remembered that Minchin has seen similar forms in *C. palpalis* starting from the *T. gambiense* of the blood.

Preparations of other Tsetses yielded forms mostly differing from the above, and from each other, though evidently belonging to the same generic group, and Novy describes three more of them. Finally he states his conviction that the probably non-pathogenic flagellates found in insects correspond with the forms met with in artificial cultures.—(F. Mesnil.)

"Arch. Institut. Royal Bacter.," Camara Pestana.

Bellencourt, A., and Trança, C., describes trypanosomes from the badger and rabbit, the latter of which proved infective to other rabbits, but not to mice, rats or guinea-pigs. They also describe a bat parasite from *Vespertilio kuhli*, of Tunis.

"Lancet," March 10, 1906.

ON THE ANIMAL REACTIONS OF THE SPIROCHÆTES OF AFRICAN TICK FEVER.

Breuil and Kinghorn.—In this preliminary note the authors demonstrate the marked pathogenicity of the spirillum brought by Todd from the Congo Free State. Their investigations were started from a monkey infected by ticks, and which died with large numbers of parasites in its blood. Peritoneal injections, usually of large doses, were always adopted. Rats were usually infected in a few hours, though in exceptional cases the stage of incubation may extend to twenty-one days, and they died in from one to forty-five days. Sometimes the animal died in the first paroxysm, and in others they survived three or four days before succumbing. The principal *post mortem* signs were hypertrophy of the spleen and numerous hæmorrhagic infarcts. Mice died in from twenty-four to forty-eight hours, with enlarged spleens. Rabbits showed spirochætes in the blood after two to three hours, their number increasing and persisting for three days, the animal dying in three to ten days. The temperature ranged from 38° to 40° during the first hour, and then remained at 40·5° to 41·5° till death. Marked changes in the spleen, liver and bone marrow. Of four guinea-pigs two died on the third day, the others were infected for forty-eight hours and then recovered. A dog and a pony showed signs of infection for three days and then recovered. A monkey, subcutaneously inoculated, showed parasites in the blood. The infection of monkeys by tick bites took place after five days' incubation, and those that succumbed showed lesions of the spleen, liver and bone marrow in the shape of anæmic infarcts and necrotic areas. They conclude that the spirochæte of tick fever differs from *S. Obermeiri*.

"Att. de la Societá per gli Studi de Malaria," 1906, pp. 125-132.

THE PRESENCE OF HÆMOLYTIC BODIES IN THE BLOOD IN HUMAN MALARIA.

Dr. Dante de Blasi confirms the previous researches of Celli, Casagrandi and Carducci in their results on the non-existence of any autolytic or isolytic properties in the blood of malaria patients. His experiments were made with an aqueous extract of malarial blood. 1 cc. of blood clot is emulsified with 19 cc. of sterilised distilled water, yielding a liquid which has itself a distinct rosy tint, so that in estimating his results the experimenter must gauge the degree of hæmolysis by comparisons with type dilutions of "laked" blood. He finds that both (1) the extract of malarial blood and of non-malarial, are alike isolytic, but the former is more so than the latter. (2) The extract of malarial blood is alone autolytic. Autohæmolysis is, however, merely frequent but not constant, and may be present in all types of malarial fever. Moreover, it is not due to the taking of quinine, as one of the cases described had taken none. Further, the author found no autohæmolytic power in the blood of persons whom he had given a gramme of quinine daily for eight days hypodermically. The phenomenon, however, cannot be referable to the malarial parasite itself, as it was demonstrated in the blood of two convalescents. By centrifuging the watery extract the author separated a deposit of leucocytes and stroma of red corpuscles, that was even more hæmolytic than the liquid itself, This property of the blood-extract resists heating to 56° for half an hour, but is destroyed by 60° at the end of an hour, and by 100° in half an hour, and cannot be restored by the addition of fresh serum. The resisting power of the red corpuscles has nothing to do with malarial hæmolysis as the author, having found that a physiological solution is hæmolytic if kept for sixteen to twenty hours in contact with a well-washed clot, demonstrated that this solution was almost as effective as the red corpuscles whether malarial or non-malarial; while in using the watery extract the malarial corpuscles are much more active than the non-malarial. Intracellular hæmolysine is not specific, as he found it also in cases of typhoid, rubeola, erysipelas and scarlatina, but in a case of anchylostomiasis the watery extract was neither auto- nor iso-lytic, while the serum possessed both powers.

Lastly, the serum of malaria and of non-malaria patients inhibits the autohæmolysis produced by the watery extracts of malarial blood.

"C. R. Soc. Biologie," T. lix., p. 19.

THE PATHOGENY OF BILIOUS HÆMOGLOBINURIC FEVER, AND ITS TREATMENT BY CHLORIDE OF CALCIUM.

Vincent, H.—According to the writer this form of fever appears in malarial cases under the influence of various secondary influences, one of the commonest of which is the absorption of quinine. This drug will sometimes give rise to hæmoglobinuria even in non-malarial cases.

When due to quinine it is easy to avert the crisis by giving four to six grammes of chloride of calcium daily by the mouth, or one to two grains hypodermically, dissolved in physiological solution. The drug here acts as an anti-hæmolytic, much as it does in the coagulation of blood, or, as Delezenne has recently demonstrated, in the action of pancreatic juice. M. Laveran, however, regards the connection of quinine with blackwater fever with some reserve, as the disease is unknown in many malarious regions, and, moreover, often appears in cases that have not taken quinine.

"Semaine Médicale," April 11, 1906.

TROPICAL HYGIENE IN BRITISH, GERMAN, AND FRENCH COLONIES.

Gloaguen, surgeon in the French Navy, has published notes he made whilst cruising along the eastern coast of Africa. He was surprised to find that the British are behind the Germans in the matter of making and keeping their possessions healthy. The English fall back on their egotism and individual hygiene; the Germans on their inflexible militarism, and the French on their proverbial heedlessness.

English prophylaxis is based on two things: entire separation of the native and the European communities, and strict application of the principles of private hygiene. The English lead an active life, with athletics, &c., to keep mind and body in a healthy condition; they reside in comfortable houses, but they make no effort to render the country healthier, and improve the sanitary conditions of the natives. There is no attempt at a general plan of campaign against tropical diseases. The native quarters are left in their filth, and fall an easy prey to disease. Plague is installed in nearly all the British colonies on the Indian ocean, and with a few exceptions, no satisfactory measures have been taken even against malaria.

The Germans, on the other hand, enforce the same sanitary measures in the native as in the European quarters. Hospitals are being organised at the main points, and the country is divided into districts, each in charge of an agent empowered to enforce the sanitary regulations. Medical stations are organised along the caravan routes, and the natives are examined, registered, and given certificates. Laboratories are numerous. The streets in the native quarters have been made wide and airy, and are kept clean. The garbage is carted away daily, instead of being allowed to accumulate around the houses, as in the English and other colonies. Standing waters are drained or oiled. Quinine prophylaxis has been introduced by the Germans on an extensive scale. Wherever he went in the French colonies he constantly heard the complaint: "If only this country belonged to England, it would have been made healthy long ago." The French are now trying to introduce some semblance of the German measures into their colonies, and with some success.

"Lancet," August 4, 1906.

(1) "A Note on the Treatment of Catarrhal and Gangrenous Dysentery."

Amos, C. B. Sheldon, M.B., writing from the Hospital at El Tor, Sinai, describes his experiences during four seasons of observation. He states that (1) for slight and recent form of dysentery supervening on diarrhœa, he finds good results from sodium sulphate in drachm doses, given hourly until a fæcal stool is passed. The treatment is repeated on successive days until tenesmus is no longer complained of, and neither blood nor mucus is passed. (2) in the gangrenous form of dysentery ipecacuanha given in the usual way (30 to 60 grains ipecacuanha, half an hour after exhibiting 20 drops laudanum), is applicable and efficient in young and robust men suddenly seized with dysentery. In old and feeble patients, calomel in 4½ grains thrice daily, a treatment previously advocated, is productive of harm; calomel in minute doses of ⅛ grain, in three successive doses, is less objectionable; but calomel in any form is pernicious in dysentery. (3) Opium, by giving complete rest, is advocated by Dr. Amos in enthusiastic terms, especially in old chronic cases. Morphine, administered hypodermically, every four hours or every eight hours, as expedient, combined with sparteine or caffeine injections to combat cardiac exhaustion, is the form of administration advocated.

Rectal injections have been occasionally useful, according to Dr. Amos; sulphate of copper, 1 in 1,000, being perhaps the best, but rectal injections, when the intestine is gangrenous, are not without danger.

As regards diet, Dr. Amos states that Africans, Turks, and all Asiatics almost invariably evince a great repugnance to milk. When they can be persuaded to take it the *régime* followed is as follows: They receive half a pint of milk at 7 a.m., when those without hæmorrhage also have a small piece of bread; at 11 a.m. a plate of finely mashed rice, potatoes, lentils, macaroni, or beans, over which a little meat soup has been poured, is served round. Convalescents also have a small piece of bread. At 5.30 p.m. they have a similar meal. During the night they have a pint of milk diluted with water to the patient's liking. Those who are very weak have in addition each day the whites of four eggs beaten up with brandy or water. The yelks of eggs they cannot digest. No pure water is given, but a 1 in 3000 solution of lactic acid is placed at the bedside for them to sip at will. With this dietary blackened tongues become moist and clean in one or two days, thirst disappears, no undigested food appears in the stools, and no difficulty is found in inducing the patients to take nourishment.

(2) "A New Subspecies of *Glossina palpalis* on the Upper Congo."

Massey, A. Yale, writing from Ruwe, Congo Free State, states that at the junction of the Lufupa and the Lualaba, 10° S. lat., specimens of the subspecies *Glossina palpalis wellmani* have been found. Isolated cases of sleeping sickness have been found in the locality, but it is unknown where the patients contracted the disease.

(3) "A Case of Plague with Unusual Eye Symptoms."

Rees, Phillip, M.B.Lond., at the Fatshan Hospital, near Canton, China, has recently observed some unusual signs and symptoms of plague. In one case the submaxillary region was swollen and infiltrated to an inordinate extent; in other cases no glandular enlargement could be detected; a blood-stained discharge from the nose is recorded in one or two fatal cases. A female patient, with enlarged glands in arm and groin, and in whom abortion occurred on the sixth day of the illness, developed conjunctival hyperæmia, the pupil of the left eye became occluded with lymph, and there was slight hypopyon. In the right eye there were three patches of lymph on the posterior surface of the cornea. Atropine instillation gradually dilated the pupil, the woman, however, refused further treatment, and died whilst under the care of a native doctor.

Notices to Correspondents.

1.—Manuscripts sent in cannot be returned.

2.—As our contributors are for the most part resident abroad, proofs will not be submitted to those dwelling outside the United Kingdom, unless specially desired and arranged for.

3.—To ensure accuracy in printing it is specially requested that all communications should be written clearly.

4.—Authors desiring reprints of their communications to the JOURNAL OF TROPICAL MEDICINE should communicate with the Publishers.

5.—Correspondents should look for replies under the heading "Answers to Correspondents."

Original Communications.

THE BACILLUS OF HAMILTON WRIGHT, OBTAINED FROM TWO CASES OF ACUTE BERI-BERI.

By LEONARD S. DUDGEON, M.R.C.P.Lond.

Bacteriologist to St. Thomas's Hospital; Lecturer on Pathology in the Medical School, and Director of the Hospital Laboratories.

(From the Pathological Department, St. Thomas's Hospital).

A SHORT account will be given here of the bacillus which Dr. Hamilton Wright isolated from the duodenum and from the fæces in two acute cases of beri-beri, and which he sent to me for investigation. It will be most convenient to refer firstly to the morphological and cultural characters of the above mentioned organism, and then to refer to the experiments which were made as to the pathogenicity of this bacillus.

MORPHOLOGICAL CHARACTERS OF THE BACILLUS ISOLATED FROM THE DUODENUM.

This organism varied from 0·5 to 5 μ in length, some very long forms occurring in chains were also met with; no constant or typical arrangement was observed. It was Gram positive and stained well with basic Fuchsin and Loeffler's methylene blue. The organism did not take the stain with the same intensity throughout, some portions being much paler than others.

MORPHOLOGICAL CHARACTERS OF THE BACILLUS ISOLATED FROM THE FÆCES.

This bacillus showed no tendency to form chains, was a stouter bacillus, often found in clumps, the staining was more irregular, with a tendency to darkening at the poles, while a few of the bacilli showed definite club-shaped ends; in other respects this bacillus resembled that isolated from the duodenum.

CULTURAL CHARACTERS.

It may be stated at the outset that the organism which Dr. Hamilton Wright has isolated from these cases of beri-beri, was an obligatory anærobe. It was found to be a matter of considerable difficulty to cultivate this organism in liquid media, even under anærobic conditions. Most satisfactory results were obtained by growing it in the depths of solid media.

It will be most convenient if the cultural characters of the bacillus isolated from the duodenum and from the fæces are given in a tabulated form under the respective headings. The points of resemblance will then be very readily seen. In all instances, except shake cultures, the organism was grown at 37° C., either in Buchner's tubes or Bulloch's anærobic jars.

DUODENUM.	FÆCES.
Agar slopes. — Delicate and slightly opaque colonies appeared in twenty-four hours; they only slightly increased in size as time advanced. The full sized colonies were about the same diameter as those of a virulent streptococcus.	Ditto
Litmus milk. —No change in fourteen days.	Ditto
Glucose gelatine shake. —(22 C.). Small opaque white colonies occurred in the depth of the medium in twenty-four hours; as time advanced, the colonies slightly increased in size, were opaque and showed no tendency to produce liquefaction of the medium, even at the end of several weeks. The growth was very much more abundant in the depth of the medium than at the surface. In many instances a typical stalactite arrangement was noticed. No gas formation occurred.	Ditto
Glucose gelatine stabs.—(22° C.). A delicate growth occurred along the course of the needle and gradually became more marked as time advanced. At the end of a month the colonies were thick, opaque, white and much larger sized towards the depth of the jelly than towards the surface.	Ditto
Glucose agar slabs.—(37° C.). Similar results to the glucose gelatine slabs.	Ditto
Neutral red broth.—No alteration in colour at the end of one month's incubation.	Ditto
Drigalski and Conradi's medium.—Stab cultivations were made, but no alteration in the colour of the medium occurred after one month's incubation at 37° C., and no definite colonies were detected.	Ditto
Litmus maltose shake.—Acid, but no gas at the end of seven days' incubation.	Acid, but no gas at the end of seven days' incubation.
Litmus lactose shake.—Acid, but no gas at the end of seven days' incubation.	No change.
Litmus raffinose shake.—No change.	No change.
Litmus mannite shake.—No change.	No change.
Litmus cane sugar.—Acid, but no gas in seven days' incubation.	Ditto

PATHOGENICITY.

Saline emulsions were made from a forty-eight hours' culture on agar of the bacillus from the duodenum and also from the fæces.

Experiment A.—Two cc. of each culture were injected into the peritoneal cavity of two guinea-pigs, but neither animal was in the least way affected, and when killed at the expiration of one month, appeared to be perfectly healthy. The heart muscle was stained with Scharlach R, but failed to show the slightest evidence of any fatty change.

Experiments B and C.—Two cc. of saline emulsions from gelatine cultures were injected into the peritoneal cavity of mice and subcutaneously into guinea-pigs, but in no instance was any effect produced.

Experiment D.—A guinea-pig was fed on 2 cc. of a saline emulsion of the bacillus isolated from the duodenum, but at the end of one month the animal was apparently well.

AGGLUTINATION TESTS.

Owing to the courtesy of Dr. Stanton, of the

Seamen's Hospital, I obtained the blood from three cases of beri-beri. A forty-eight hours' culture of the bacillus isolated from the duodenum was used for the agglutination reactions.

	Period of Disease	Result
Native of Bombay	Early stage ..	Dilation 1·20, no reaction
Norwegian sailor...	6th month ..	,, ,,
Native of Calcutta	Six weeks. (Several cardiac attacks during the past few weeks.)	,, ,,

Conclusions.

(1) From the investigations which I have made it seems probable that the bacillus isolated from the duodenum and that isolated from the fæces are one and the same organism. The only points of difference are slight variations in their morphology, and that one of them acidifies lactose, the other not.

(2) There was nothing in this investigation to show that the organism of Hamilton Wright is related to beri-beri. It has been found to be non-pathogenic to mice and guinea-pigs, and the serum obtained from three cases of beri-beri during various stages of disease, failed to produce any agglutinative reaction on this bacillus.

Of course, one must be fully alive to the fact that, although this bacillus is non-pathogenic to mice and guinea-pigs, and did not agglutinate when tested with the serum of three cases of beri-beri, it may, yet, be the cause of the disease, but this seems to me improbable.

BERI-BERI; MOULDY RICE: THE OCCURRENCE OF BERI-BERI IN THE SOKOR DISTRICT.

By John D. Gimlette, M.R.C.S.Eng., L.R.C.P.Lond.

The inference that beri-beri, as it occurs in British Malaya, is due to mouldy rice was taken some years ago as the basis of an argument by Mr. Leonard Braddon, F.R.C.S., State Surgeon of Negri Sembilan, in the Federated Malay States [1]. It excited a good deal of local discussion at the time, and the mouldy rice theory was again lately revived by Dr. S. Lucy, Colonial Surgeon, Penang [2], and still more recently urged by Charles Hose, Esq., D.Sc., Divisional Resident of Sarawak, in North Borneo [3].

It is a theory, and there are many who are not satisfied with the circumstantial evidence which has been brought forward to support it, while there are others, notably, Dr. E. A. O. Travers, State Surgeon of Selangor, who have decidedly disagreed with Mr. Braddon's original contention that the probable cause of beri-beri is a toxin conveyed in certain forms of rice [4].[1]

[1] Many others who have spent years in exhaustive research work on Beri-beri have entirely rejected the rice theory. The cause of beri-beri, however, has not yet been definitely proved by them to Science, and for this reason I think that any new evidence which appears to support the rice theory is worthy of their attention.

The following notes were taken in the interior of Kelantan, a distant State in the Malay Peninsula, about 350 miles north of Singapore. Three years ago mining operations were commenced in Kelantan by a British Syndicate which was soon formed into a large Company, to which I was appointed the first resident medical adviser. The native state of Kelantan had not hitherto been explored by any European miners. It was therefore a typically new country, with new mines, and, beri-beri being such a well-known local scourge among Chinese, some anxiety was felt in the early days of the Company as to the health of the newly imported gangs of coolies that were necessary to carry on the work of underground mining.

Chinese labour is universally employed for this purpose in the Malay Peninsula, but, curiously enough, this mining district in Kelantan (afterwards referred to as the Sokor district), remained at first remarkably free from beri-beri. No cases were diagnosed in 1903.

Mining operations were commenced in the interior of Kelantan, in a valley some seven miles distant from a small station on the river Sokor; the general welfare of the Company's coolies was quite as well, if not better, cared for as compared to that in similar mining districts; the meteorological conditions—all very favourable to the formation of moulds—were found to be more or less the same as those in other parts of the Malay Peninsula; the coolies were fed upon imported Rangoon rice, as is customary in other mining camps in this part of the world.

Rangoon rice is more liable to be attacked by moulds and weevils than any other kinds of imported rice [3]; it is also more difficult to clean for cooking, as it soon becomes broken in the necessary process of kneading and washing, but it is cheap and is in common use. The supply was mainly obtained by the Company from Singapore, because the conservative Chinese do not care to purchase rice which is grown locally and only roughly husked by indolent Malays for retail; moreover, the Company had endeavoured to store Kelantan rice, but found that this was impracticable, as it very quickly deteriorated after it had been husked by hand and stored.

As there was no market in the Sokor district it was necessary to stock a comparatively large amount of rice for the Chinese miners; this was all kept, at first, in a small store at the river station in bags, each of which generally contained from 1 to 1½ pikuls of rice. The pikul is a Malay measure of weight in everyday use; it is approximately equal to 133¼ lbs. avoirdupois, and is divided into 100 catties, each catty roughly corresponding to 1⅓ lbs. avoirdupois.

Why Rice Deteriorates.

These large bags were all piled in a small space, one on top of another to a height, and being fairly heavy were difficult to interchange. When a large supply of rice came in, the new bags were invariably placed on the top of the old pile. This was unfortunate, as was afterwards proved, because, long before the delivery of the rice on the bank of the river Sokor it was exposed, as rice in the husk, to deterioration through damp. The writer of an article on "A Trip to Burma," recently published in the local press, says, when describing the railway journey from Ran-

goon to Mandalay: "A resident of the country told us that the paddy owners often had to wait a month before the railway could take their grain. We saw stacks and stacks of it—in bags—lying out in the open alongside the line near railway stations" [5]. The rice is shipped from Rangoon to Penang, and from there to Singapore.

Dr. Lucy also mentions that when large consignments of this rice to the Straits Settlements coincide with an interval between the crops in Rangoon, the only supply at these times is of an inferior quality left over from the last crop. Such an interval occurs in October. As regards Kelantan, delays occur in shipping from Singapore, as well as delays and boating accidents on the Kelantan rivers, especially during the violent weather of the North East monsoon season, which is mostly felt during the months of November, December and January.

Local means of communication with the Sokor district, again, are very slow; under ordinary circumstances six or seven days are taken in transporting cargo by river boats to the headquarters of the Company, located about fifty miles inland from the coast; from there it has to be transhipped into much smaller boats for transport up the river Sokor, which is a small stream in the adjoining Sokor district. Another four days would be taken before it was finally distributed in the mining camp, making a fortnight from Singapore even in good weather.

Some idea of the bad weather during the North East monsoon season may be gathered from the records of rainfall in Kelantan. The rainfall in the Sokor district was 27·99 inches in December, 1904; 17·42 inches for the month of November, 1905; 10·97 inches in December, 1905, and 28·48 inches for January, 1906.

Mining coolies or their contractors obtained rice, from time to time, in small quantities by means of an order in writing on the clerk in charge of the river store and carried it through the jungle to the mine. There was a tendency on the part of the contractors to apply for large quantities of rice at the beginning of the month, but it could not always be delivered to them then, on account of occasional difficulties with the jungle transport. Their applications varied according to circumstances, and their only means of supply was through the river store. The main rivers in Kelantan may rise to a height above 30 feet during the wet weather, and there are then corresponding floods in the smaller streams, such as the Sokor river and other small rivers in the district. Good judgment was therefore essential in order to keep a fair balance between the supply and demand for rice at the river store. The native clerk in charge of the store was an intelligent Sumatran who was appointed in 1903.

Prevalence of Beri-beri.

Little concern was felt as regards beri-beri during the greater part of 1904, although the number of Chinese workmen was greatly increased. There were, for instance, only eight cases of this disease registered, with two deaths, a mortality which was trifling when compared to an appalling death-rate of 79·99 per cent. (187 deaths out of 234 cases), as I had known it in one of the mining districts of a neighbouring State [6].

Towards the close of the year, however, the general health of the Sokor district was far from satisfactory, malaria was very prevalent in the mining camp, which had always been topographically unfavourable to health. Special attention was accordingly paid to sanitation, and some expense as well as much trouble was incurred in trying to render the camp more healthy, but it was, nevertheless, unsatisfactory to report, at the end of June, 1905, that a number of cases of beri-beri had occurred. There had been 37 cases with 7 deaths.

The coolie gangs had been increased by about 100 men as compared to 1904, bringing the whole strength up to 400 Chinese. Among them were a number of inexperienced new comers from Singapore, who had been engaged by a Chinese contractor in May under conditions similar to those of the "Singkheh" or indentured Chinese labourer of the Straits Settlements.

The bad health of the "one year contract Singkheh" is notorious in the Malay Native States, and these new arrivals in Kelantan suffered, as might have been expected, considerably more than older "Lowkhehs" or time expired Singkhehs would have done. Twelve of them died from various causes in a very short time, six of them from beri-beri in July.

Many of these untrained Chinese were lodged in some newly-erected coolie lines, and it was thought at the time that they were being affected by reason of a somewhat extensive disturbance of the soil which was found necessary when erecting their buildings. As beri-beri has been thought by some to have an indefinite connection with disturbance of the soil in the Tropics [7], stress was laid on this fact; greater attention was paid to sanitation; old buildings were destroyed; the ventilation and hygiene of the camp generally improved, and overcrowding prevented as far as possible.

Table A.

Showing the Incidence of the Disease in 1905.

Months	New Cases	Deaths	Nationality			Treated in Hospital	Treated as Out-patients
			Chinese	Javanese	Malays		
January ..	6	5	2	4	..	5	1
February ..	..	1	..	..	..	..	..
March ..	2	..	2	..	..	..	2
April	1	..	1	..	..	..	1
May	10	1	9	1	..	4	6
June	18	..	17	1	..	7	11
July	28	6	28	..	..	8	20
August ..	10	1	10	..	..	..	10
September ..	4	..	4	..	..	..	4
October ..	5	..	5	..	..	..	5
November ..	9	2	9	..	..	1	8
December ..	12	1	7	..	5	1	11
Total ..	105	17	94	6	5	26	79

The principles of sanitation in the Tropics were now very strictly enforced, and at the end of the year a great diminution in the prevalence of malaria was the result, but it was vexatious to find that there had been 68 additional cases of beri-beri with ten more deaths from this disease. The incidence of the outbreak is shown in the attached table A.

With regard to this table it is important to note that the total strength of the mining coolies was reduced by more than one half during the last five months of the year. The reduction began in August, and by the end of the year there were only about 100 Chinese miners left at the works. Under the heading "new cases" only different individuals are included; the death which occurred in February was a case which had remained over from January. It is only of passing interest to notice that, as regards seasonal prevalence, by far the greater number of cases occurred during the months of the south-west monsoon, namely, from April to September inclusive. The greater number of coolies were employed during these months. The influence of the north-east monsoon on the supply of rice will be seen later.

TABLE B.

SHOWING THE CLINICAL FEATURES OF THE FATAL CASES IN 1905.

Date, 1905	Nationality	Subjective Symptoms	Died, 1905
Jan. 1	Javanese ..	Slight previous fever, weakness, orthopnœa, sudden cardiac pain and vomiting	Jan. 14
,, 1	Javanese ..	Admitted for ulcer of leg, swelling of legs and body followed, died suddenly	Feb. 20
,, 13	Ch. Kheh..	Debility, shortness of breath, swelling of legs and face	Jan. 14
,, 14	Ch. Kheh..	Sudden severe cardiac with hepatic pain and orthopnœa	,, 14
,, 18	Javanese ..	Previous fever, weakness, swelling of whole body and extremities, sudden cardiac pain	,, 29
,, 31	Javanese ..	Anæmia, debility, dyspnœa, tenderness of legs, with sudden cardiac and hepatic pain	,, 31
June 28	Ch. Kheh..	Previous fever, numbness and tenderness of legs, with general œdema	July 8
July 1	Ch. Hailam	The same as above	,, 7
,, 2	Ch. Hailam	The same as above	,, 15
,, 5	Ch. Kheh..	The same as above, with hepatic pain	,, 9
,, 10	Ch. Hailam	The same as above	Aug. 14
,, 24	Ch. Kheh..	Second attack, great cardiac pain and dyspnœa, died suddenly	July 24
Nov. 2	Ch. Kheh..	Previous fever, swelling of whole body and dyspnœa	Nov. 9
,, 24	Ch. Hailam	The same as above, with greater swelling	,, 24

The date in the table above refers to the day on which the patient first applied for relief.

The incidence of the outbreak was characterised as follows: in January it occurred in the acutest form of the disease, all the cases died. In the second week there were three sudden deaths within twenty-four hours. The outbreak was mainly confined to the Javanese who were employed as timber cutters, 33 in number, and was so unexpected as to arouse the private suspicion that the patients had been poisoned by their contractor for the purpose of gain. The cause of their deaths, however, was investigated, and all the cases were registered as due to acute beri-beri.

In May an equal number of cases occurred in each half of the month; the same happened in June, but in July, when the disease was at its height, 18 cases out of the total occurred in the first half of the month. The total Chinese strength was then also at its maximum. In August, 8 cases occurred in the first half of the month, and in November again 5 in the first half of the month. In December, it attacked the Malays for the first time and was seriously affecting the Chinese; of the total number treated 9 applied again for relief during the first half of the month. The death rate for beri-beri in 1905 was 16·19 per cent. for cases treated, the greatest mortality occurring in January, July and November. In every instance the disease was of the so-called wet variety; the chief clinical features of the cases which were fatal during January, July and November are shown in table B.

ASSIGNED CAUSES OF BERI-BERI.

It was part of my duty to visit the Sokor district twice every quarter, and to leave a written report before returning to headquarters. The importance of improved sanitation as a check to beri-beri was frequently referred to in my reports, but the possibility of mouldy rice being a vital factor in connection with the disease was, unfortunately, overlooked until the last month of the year. In the second week of March, however, I examined the diets of the Javanese and reported that their rice was of good quality, but not sufficiently cooked. The Chinese themselves in the Sokor district do not regard mouldy rice as even a probable cause of beri-beri; on being questioned as to the cause they almost invariably refer to exposure to the very cold water in the underground workings or to the drinking of bad water.

The Sokor district hospital is in charge of a Chinese dresser (corresponding in rank to the Indian hospital assistant); this dresser was specially chosen in 1904, partly on account of his experience of beri-beri. He had formerly been in the F.M.S. Government Service under me, and was, at that time, stationed in the mining district, where the death rate from beri-beri was as high as 79·99 per cent. of cases treated.

Late in December he called my attention to the diet which was then in everyday use in the camp, and collected, on December 20th, samples of the rice which was being prepared for the meals in the coolie lines on that day. I examined and found that these samples were full of the live larvæ of a small light brown moth and that the grains of rice were clotted with excrementitious matter. The worst sample was one taken at the coolie lines occupied by some Chinese miners under contract to a Hailam named Ah Juan. This contained, in addition, a few small beetles, as well as the well-known rice weevil, *Calandra oryzæ*, *L.*

At the coolie lines the Chinese cooks were trying to clean this rice by hand after drying it in the sun, and

then washing by kneading it, by means of their feet, in perforated empty kerosine tins. As soon as it was sufficiently clean to the naked eye it was cooked in the usual way, that is to say, it was put into a large iron cooking pan (a kwalli), containing boiling water, stirred and boiled until it was cooked and then finally allowed to steam under the cover for about half an hour, when it was ready to be eaten either hot or cold. Water for washing and cooking was obtained from a small stream running through the camp.

Three of the Chinese cooks employed contracted beri-beri, one in the month of May, one in August, and another in October, each after about two months' work in the coolie lines. These cooks were, as is characteristic of their race, mixing good rice with the bad in order to deceive the coolies. They cooked rice twice a day in accordance with the usual Chinese custom; it was their staple diet, meat being seldom eaten.

It is important to note here, that all the rice at the river store had, at the close of the year, been transferred to a new store house which had lately been built at the mine. The river store house, only 13 feet by 18 feet and about 10 feet in height, had become too small. The rice was transferred from there during the months of September, October, November and early in December, the fresh supply of rice for December being carried direct to the mine. As soon as the bad rice was discovered in December, an examination of all the rice in the new store was held, and it was reported that a large quantity of it was unfit for consumption. I saw that most of it was infested by the same kind of worms and insects mentioned above, but by careful winnowing more than half of it could be rendered, to all intents and purposes, similar in appearance to good rice. There were several bags also in which the rice was greenish, sour-smelling and distinctly mouldy; the sacking was caked inside with rice which had obviously decayed owing to exposure of the bags to water.

Deteriorated Rice an Apparent Factor in the Etiology of Beri-beri.

It is now of interest to try and trace the connection, if any, between the occurrence of beri-beri in the Sokor district and the variation in quantity of fresh rice supplied from the local store, and I think it will be admitted that this particular outbreak appears to have been coincident with the use of deteriorated rice.

In the year 1904, all the eight cases of beri-beri occurred in the first two months of the year, one in January and the other seven in February; they were all Chinese, the one in January died suddenly and another almost suddenly in February. At this time the coolies, who were for the most part newly arrived Hailam miners, were working on the top of a high hill, which caused their local means of communication to be even a little more difficult than was usual. Five of the 8 cases occurred among the Hailam miners; they had all eaten deteriorated rice.

At the end of 1903, there were 119.24 pikuls of rice in the river store, much of which must have been at the bottom of the pile for some time, no fresh rice was received in January, 1904, but 60.58 pikuls were issued, leaving 58.66 of the original balance from 1903; in February, only 27 pikuls were received, and by the end of the month 73.96 pikuls had been issued. The greater part of the old rice was therefore used up in the month of February. The balance in hand at the end of the year 1904 was 104.06 pikuls of rice. With the exception of the month of February, when the amount of rice in store at the end of the month was only 12.40 pikuls, the balance of rice at the end of each month varied between about 30 and 90 pikuls throughout the year, but the amount was slightly greater during the last two months, when provision was being made for the north-east monsoon season. There was never a great surplus of rice in stock in 1904.

The Sumatran clerk in charge of the store told me that he always, so far as possible, endeavoured to interchange the bags, and this would have been feasible provided the supply of fresh rice was moderate in amount.

It was impossible to attempt to trace the local issues of the bags originally imported from Singapore, because the larger bags containing 1½ pikuls of rice were made up into smaller ones at the river store in order to facilitate their transport through the jungle to the mine; the small bags had no distinguishing marks, but through the courtesy of the General Manager of the Company I am able to show the exact amount of fresh rice that was stored during the year 1905.

The accuracy of the data given in the attached tables C and E can, I know, be relied upon, they have been prepared for me by the Chief Accountant of the Company. The figures, although complicated, are worthy of close attention.

In connection with table C, it is very important to remember that there can be no doubt that the tendency was to pile the bags of fresh rice on top of the older ones, and that until the rice began to be transferred from the river store many of the oldest bags were necessarily at the bottom of the stacks.

Table C.

Showing the Variation in Quantity of Fresh Rice in use in 1905.

Months	Amount of fresh rice stored during the first half of the month	Total amount of rice issued during the first half of the month	Amount of fresh rice stored during the second half of the month	Total amount of rice issued during the second half of the month
	Pikuls	Pikuls	Pikuls	Pikuls
January	16.93½	93.00	92.09	23.45
February	79.86	46.95	86.04	18.35
March ..	16.01	57.30	54.23	24.07
April ..	120.36	40.67	23.96½	76.20
May ..	6.82	82.58		40.82
June ..	81.79	84.93	87.83	27.12
July ..	136.95	75.44	100.74	27.30
August ..	111.60½	64.90	25.27½	30.32
September	86.06½	95.45	163.81½	20.70
October ..	84.76½	67.11	39.24	51.00
November	24.30	62.97	54.13½	24.50
December	23.88	41.70	—	25.10
Total ..	789.34	813.00	727.36	388.93

An examination of the above table shows that a very large quantity of fresh rice was stored throughout

the year but the store was very short of fresh rice in the first half of January. The 16.93½ pikuls was delivered in two consignments, one of which (5.96½ pikuls) was received as late as the 7th of the month and the other (10.97 pikuls) not until the 9th of January. It follows therefore that 76.03½ pikuls of the old rice left from 1904 were used, and that 27.99½ pikuls of it remained in the store.

Very little fresh rice was received in May (only 6.82 on the 4th of the month), but the maximum 249.88 pikuls was received in September, as well as large amounts (165.90 pikuls) in February, and 237.69 in July, but only 78.43½ in November, the greater part of which came in on the 20th of that month.

A more critical examination of table C. shows that 96.63½ pikuls of rice were in stock at the end of January, and it will be remembered that of this amount 27.99½ pikuls remained from the old stock of 1904; by deduction it will be found that, disregarding this amount of 27.99½ pikuls for the present, the remaining 68.64 pikuls may have remained untouched until the first half of June, when 3.14 pikuls of this old rice must have been issued. At the end of May, exclusive of the 68.64 pikuls, there would have been only 28½ catties of fresh rice in hand. In the first week of June the greater part of the fresh rice (48.86 pikuls) was not received until the 13th day of the month and by far the greater quantity of rice was issued in the first half of this month as compared to the second half, and again, as regards the supply of the second half, 47.35 pikuls were received as early as the 18th of June. The labour force, it will be remembered, was greatly increased in May by a number of unacclimatised coolies.

It is not possible to supply an accurate statement of the days on which the rice was actually received by the Chinese contractors and other natives, through reason of the carelessness with which they presented their orders for rice at the store, but it may safely be presumed that the 68.64 pikuls with the old stock (27.99½ pikuls), was in use about this time and that the oldest of it had greatly deteriorated. This is corroborated by the Sumatran clerk, who tells me that he went on leave in February and found on his return in May that his substitute had neglected to endeavour to interchange the bags.

At the end of June, 126.55½ pikuls were in stock, including probably much of the 27.99½ pikuls left over from 1904, and on referring again to the bills of lading of the boat service, I found that the greater part (97.70 pikuls), of the fresh rice for the first half of July did not arrive until the 8th day of this month, while the greater part of that received in the second half (71.07 pikuls), came in as early as the 17th of July.

The Mining Accountant at the Sokor camp has kindly given me a note of his weekly balances of the rice in stock at the river store from May, 1905, until December; they were lowest on June 17th (90.68 pikuls), on June 9th (90.98 pikuls), on May 27th (94.61½ pikuls), on May 30th (126.96 pikuls), on June 24th (125.31 pikuls), and on July 1st, when there were 140.61 pikuls.

There can be no doubt, I think, in concluding that either stale or greatly deteriorated rice was in use at the end of December, 1904, during the first half of January, 1905, in May, at the beginning and end of June, at the beginning of July and probably at the end of July; it was found in use in December, 1905, after the rice had been transferred from the river store to the new store-house.

A brief summary of the clinical history of the disease shows that beri-beri occurred markedly in the beginning of January, 1905, in May, in June, very markedly in the beginning of July, and in the beginning of August, and as the rice was transferred in September by means of a limited number of bullock carts, in the process of removal it may, I think, be reasonably supposed that the oldest bags of rice then came into circulation, but this may have been delayed owing to the very large supply of fresh rice which was received in September, on account of the coming of the north-east monsoon season.

In September and October the advance of the disease was arrested, but only to again progress in November and December.

The labourers in the Sokor district comprise chiefly Chinese, and for surface work a few Javanese and some Kelantan Malays. The Chinese are divided into two classes, the Hailams, who are immigrants from Hainam, and the Khehs, who come from a district north of Canton. Both classes form the mining coolies and each work in separate gangs under a contractor or contractors of their own class. Besides Chinese miners there are a few fitters and other Chinese who are not working under contract. The proportion of cases and deaths from beri-beri among the Chinese is shown below in table D.

TABLE D.

SHOWING THE PROPORTION OF CASES AND DEATHS AMONG THE CHINESE IN 1905.

Months	Hailams under Contract		Khehs under Contract		Other Chinese		Treated in Hospital		Treated as Out-Patients	
	Cases	Deaths	Cases	Deaths	Cases	Deaths	Cases	Deaths	Cases	Deaths
January ..	—	—	2	2	—	—	1	1	1	1
February ..	—	—	—	—	—	—	—	—	—	—
March	—	—	—	—	2	—	—	—	2	—
April	1	—	—	—	—	—	—	—	1	—
May	4	—	2	1	3	—	5	1	4	—
June	11	—	6	—	—	—	10	—	7	—
July	18	2	9	3	1	1	8	5	20	1
August ..	2	—	6	1	2	—	—	—	10	1
September ..	1	—	2	—	1	—	—	—	4	—
October ..	—	—	5	—	—	—	—	—	5	—
November ..	5	1	4	1	—	—	8	1	1	1
December ..	6	1	1	—	—	—	6	1	1	—
Total ..	48	4	37	8	9	1	38	9	56	4

It will be seen that the Hailams suffered most in July—18 cases with 2 deaths, also the Khehs in July —9 cases with 3 deaths, and that the only death which occurred among the other Chinese was in July. On turning to the hospital registers it was found that out of the 18 cases reported during the first half of July, no less than 13 occurred during the first week,

and that all the deaths, as shown in table B happened, with the exception of one, to be in the first half of the month. All the cases mentioned in this paper were of the male sex; there were only three Chinese and very few Malay women in the camp.

Reverting to the supply of rice from the store it may be seen that the Hailams and the Khehs, as well as the other natives, obtained very large supplies of rice during the months of May, June and July, but comparatively little in February. The amount purchased by them and other natives is shown in table E.

TABLE E.

SHOWING THE AMOUNT OF RICE PURCHASED BY CHINESE AND OTHERS IN 1905.

Months	Hailam Contractor	Kheh Contractor	Other Chinese	Javanese	Malays
	pikuls	pikuls	pikuls	pikuls	pikuls
January	44.49	15.00	5.50	7.40	15.39

December ..	16.00	24.00	1.50	4.50	9.00
Total ..	393.61	376.00	46.10	44.50	117.71

BERI-BERI AS IT AFFECTS MALAYS.

It is now of telling interest to refer to the outbreak of beri-beri among the Malays and Javanese in the Sokor district. Malays, speaking generally, have no tendency to beri-beri, and they do not, as a rule, eat imported rice, but prefer to eat that which they plant and grow in their own country.

This rice is very seldom stored by them in their houses, unless in the form of paddy or rice in the husk; we have seen that this is very liable to go mouldy if stored. The natural custom of the Malays is to pound small quantities of their paddy into rice for cooking, and use it fresh, from day to day, as may be required for their household use. This exertion is undertaken by the women folk, who do not, as a rule, follow their people to the mining camps. One of the Malay patients in the Sokor district told me that although the Rangoon rice was very convenient, he could not afford to buy it all the year round as it was so much more expensive than the Kelantan rice, and he remarked naïvely that it always smelt of the bag even after it had been well washed and cooked.

The Malays in the Sokor district have always been in the habit of buying most of their rice at a village called Kusial, some fifteen miles distant, but, during the north-east monsoon season, owing to the wild weather and to the greater difficulty of jungle transport, they always buy Rangoon rice from the company's store in comparatively large amounts, as may be seen in Table E. It is significant that these Kelantan coolies, among whom beri-beri is unusual, should have escaped in June and July but should have succumbed in December, when they were eating the bad rice.

The weather in January, 1905, was remarkably mild for the north-east monsoon period, the total rainfall for this month only being 5·22 inches, and, under these circumstances, Malays could have obtained Kelantan rice from the village of Kusial. Malays in the Sokor district are too independent by nature to associate intimately with the Chinese, but will fraternise and eat rice with the Javanese. It will be noticed that the latter also laid in a comparatively large supply in January, February, and December, and probably for the same reason, but their mode of buying it from the store was quite different. The Malays invariably buy rice from the store in small quantities of about 40 to 80 catties at a time. The Javanese, who cannot so well afford the time to go to and from the store so often, always take their supply in bulk; for instance, in January they took the whole of their rice (7.40 pikuls) on one day, and in June their 7 pikuls in two portions on the 3rd and 15th of the month. In March, when I examined their diets, there was a good supply of fresh rice, namely, at the end of February, 169.24 pikuls (deducting again the 27.99½ pikuls), rather less at the end of March (158.11 pikuls), and a good supply at the end of April, namely, 185.56½ pikuls. It is curious that there were no cases of beri-beri among all the nationalities in February; only two in March among the Chinese, and one in April, months in which there was a good supply of fresh rice in use, and it may be of importance to recollect that rice, although mouldy or infested with worms, may be dried and winnowed in such a way that there is no apparent difference to the naked eye between it and rice which is known to be good.

EXPERIMENTAL TESTS.

The only experiments which I was in a position to make were of a simple nature. Equal quantities (two ounces) of fresh Rangoon rice, mouldy rice and rice infested with worms were well washed, thoroughly cooked and set aside in the open air for forty-eight hours. At the end of that time a greyish mould appeared first on the mouldy sample and this was quickly followed by a light brick-red mould, which in point of time next formed on the sample taken from the bag infested with worms, but only appeared slightly on the sample of fresh rice at the end of the third day. Fresh Siamese and fresh local Kelantan rice were treated in the same way and the pink mould did not appear on either until the third day, and then first in point of abundance on the Kelantan rice. From the preceding experiments it would appear that mould on rice is not destroyed by boiling, as it formed sooner on the bad samples of rice than on the good samples.

It seems not unlikely that Chinese cooking pans, unless thoroughly cleaned daily, might become contaminated in this way, as well as tubs of water in which rice bowls and spoons are washed on the conclusion of a meal, by reason of rice falling into the tub and decomposing therein.

To remark, in conclusion, on the occurrence of beri-beri in the Sokor district, a small place in the jungle of a new country, where the means of communication

are not good and where it is necessary to store a large quantity of imported rice, no management, however carefully thought out, could, I think, prevent a loss through deterioration. It is the usual experience in all mining camps in this part of the world, where climatic conditions are very unfavourable for the storing of this kind of food supply. I think it would be unfair also to brand Rangoon rice in particular as being specially unwholesome; most, if not all, of the other varieties of rice for sale in the East would, I think, sooner or later deteriorate in the same way under the same conditions. A solution of the difficulty in fertile places where rice in the husk can be obtained cheaply, might be to mill the local rice on the spot in such quantities as may be required from time to time, but other cereals, especially those which are supplied in bags, may also become mouldy or otherwise deteriorated. Besides these, also in local use, are sago and tapioca, which are exported to Europe from Singapore, as well as "dal," a small green pea which is imported, and three or four varieties of beans which are used locally, especially by the Chinese, who also favour two kinds of dried mushrooms.

I am indebted to Mr. W. Graeme Anderson, of the mining department of the Company, as well as to the General Manager and the Accountants for the help which they have given me in preparing these notes.

THE ACTION OF THE SERUM OF VARIOUS MAMMALS ON THE PLAGUE BACILLUS.

Lamb, G. and Forster, W. H., from experimental research in the serum of man, monkeys, horses, oxen, sheep, goats, rabbits, guinea pigs, and rats, conclude that no bactericidal action against the bacillus pestis is resident in the serum of any of these animals. In fact, the serum of all the animals mentioned proved to be an excellent medium of cultivation. To whatever, therefore, the immunity of some animals against plague is due, it would not seem to be resident in the serum.

RONTGEN RAYS IN MALARIA.

Demarchi, A., concludes from experiments that X-rays have no effect on the course of malarial fever, either as regards relapses or on the development of the parasites. The reduction of the size of the spleen noted after treatment by X-rays only sets in when the parasites have disappeared from the blood by medicinal treatment.

Business Notices.

1.—The address of the JOURNAL OF TROPICAL MEDICINE is Messrs. BALE, SONS & DANIELSSON, Ltd., 83-91, Great Titchfield Street, London, W.

2.—All **literary communications** should be addressed **to the Editors.**

3.—All **business communications** and **payments,** either for subscriptions or advertisements, should be sent **to the Publishers** of the JOURNAL OF TROPICAL MEDICINE. Cheques to be crossed The Union Bank of London, Ltd.

4.—The Subscription, which is **Eighteen Shillings** per annum, may commence at any time, and is payable in advance.

5.—Change of address should be promptly notified.

6.—Non-receipt of copies of the Journal should be notified to the Publishers.

7.—The Journal will be issued on the first and fifteenth day of every month.

Reprints.

Contributors of Original Articles will be supplied FREE with six copies of the Journal if a request accompany the MS. If reprints are required they will be supplied by the publishers, if the order is given with remittance when sending the MS. The price will be as below:—

50	Copies of four pages,		5/-;
100	,,	,,	6/-;
200	,,	,,	7/6;
50	Copies beyond four up to eight pages,		8/6;
100	,,	,,	11/-;
200	,,	,,	14/6.

One page of the Journal equals 3 pp. of the reprint.

If a printed cover is desired the extra cost will be for 50 Copies, 5/6; 100 Copies, 6/6; 200 Copies, 7/6.

BRITISH SPAS SUITABLE FOR TROPICAL RESIDENTS.

HARROGATE.

EVERY one knows about Harrogate, although they may never have been there, and we are reminded of its existence from time to time by elegant pamphlets detailing its virtues. Perhaps more than any other Spa in Britain is Harrogate visited by patients from warm climates in summer; they are sent thither by their doctors for the most part, but as often as not the doctor is asked, "Do you think Harrogate would suit me for a change?" Patients from the tropics suffering from the common Tropical ailments of liver or malaria do well at Harrogate during Summer. For such patients the seaside is useless, and worse than useless, it is harmful.

During the months of July and August those who have come home with malaria, anæmia, and enlarged spleen are almost certain, if resident in a town in the South of England, to get fever, probably of a remittent type, for two or three years after settling at home. Nor does the trouble cease there, for as the hot weather of July returns during several, it may be many, subsequent years, ailments such as neuritis, gastric catarrh and hepatic congestion, lumbago and several minor but annoying and depressing conditions

seem to assert themselves. What is to be done with patients suffering from their summer relapses of old malarial infection? Send them to a seaside town on the South Coast, because it is the nearest approach obtainable without going abroad to the climate from which they came? No, the sea level favours hepatic congestion, and the malarial parasite or toxin thrives in the warmth. Send the patient to a Continental Spa? People who have been abroad for many years do not want to be sent away as soon as they reach home; if they are ill they do not care to be amongst strangers, and if they are suffering from any form of tropical ailment they would be well to keep away from Continental Spa doctors, whose practice consists of "curing" the congested livers of over-fed European residents, and not the run-down tropical-marked and bleached specimens of humanity one is wont to meet with amongst old Tropical residents. A Continental Spa? No! Where, then, are there any principles to guide us in choosing a place of "cure?" High ground, bracing air and a fairly cool atmospheric temperature are the three requisites for a place suitable for "delicate" tropical residents in the months of July, August and September, for at least five years after their return from the Tropics. In England we must go northwards for these requisites, and at Harrogate, Buxton and Matlock we find for the most part what we require.

The Harrogate urban authorities are evidently quite alive to the commercial value of an impressive and pleasant environment to enhance the attractions of their valuable possession—the mineral springs. The Stray, an open space really of some 200 acres, runs through the centre of the town; its well-kept paths and plots testify to the attention bestowed upon them. The Royal Baths building in Harrogate is acknowledged to be the finest in Europe, and yet few English people have ever even heard of them. Continental spas and their doctors' names they know intimately, and can tell off-hand the nature of the waters at each and the ailments they are good for; but British Spas, their waters and their doctors are unknown to the majority, and, as usual, the Briton's ignorance of what he has in his own favoured isle is supreme. What is it that is wanted? A kursaal, beautiful walks, interesting surroundings, or is it medicinal waters, baths and treatment. In Harrogate there are all these, and there is the cool bracing air of Yorkshire, which is perhaps the greatest attraction of all. The advice to be given to tropical patients resident in England as to where to go in summer, is simple enough. Harrogate or Buxton in England; Morayshire, Nairnshire or the east of Ross-shire (Strathpeffer) in Scotland; or inland in Norway. At other seasons of the year there are British spas further south, where the invalid from the tropics will find himself or herself in congenial surroundings. Each place has its season, and, by judicious selection, the resident abroad can spend his leave or choose his holiday at places within his native shores—at home, in fact, for any part of Britain is home to those who have been long resident abroad.

The mineral waters of Harrogate are, however, after all, the essence of the "cure." This fact is apt to be forgotten, not only through the attractions and environment of the town, but the varieties of treatment at the baths are so numerous and so elaborate that the medicinal properties of the waters run a chance of being relegated to a position of but little importance. This should not be so; at any place we can have douches, needle baths, liver packs, massage with all its infinite and detailed varieties; but the Harrogate waters are Nature's gifts, and it is for these we seek after the place. Harrogate is doubly gifted in this respect, for it has a sulphur water, and a chalybeate and iron water. We cannot supplant natural waters by any artificial laboratory production. The chemist's analyses may be perfect, and his synthetical combinations may be exact; yet he cannot give us what Nature supplies to us. So it is with the mineral waters, we must go to them; they cannot be brought to us, nor made for us. Were we to attempt to imitate the sulphur waters of Harrogate by prescription, it would extend to a length which even the physician fond of drugs would scarcely dare to imitate. The constituents of these waters consist of: Sodium sulphydrate, sodium sulphide, barium chloride, strontium chloride, calcium chloride, magnesium chloride, potassium chloride, lithium chloride, ammonium chloride, ammonium carbonate, sodium chloride, sodium silicate, magnesium bromide, magnesium iodide, calcium carbonate, magnesium carbonate, ferrous carbonate, potassium carbonate, sodium carbonate, sodium iodide, barium sulphate, barium carbonate, strontium sulphate, strontium carbonate, calcium sulphate, sodium nitrate, silica, sulphuretted hydrogen, carbon dioxide, carburetted hydrogen, nitrogen.

The effect of the combination of these salts and gases upon each other, who will venture to elucidate? and the physiological chemist may well stand aghast when asked to state what their combined effect may be when introduced into the human alimentary canal. Yet such is Nature's plan of prescribing, and we are left in wonderment, wholly incapable of imitating or understanding her methods of combination to effect a cure.

(*See also Cheltenham, p.* 274).

THE DEPRECIATION OF THE ATTRACTIONS OF THE INDIAN MEDICAL SERVICE.

In previous articles we have already drawn attention to some of the causes that tend to mar the efficiency of the Indian Medical Service and to lessen its attractiveness as a field for professional enterprise, but have hitherto confined ourselves to points of a public character rather than to those that concern the prosperity of the individual officer. On the present occasion, however, we propose to consider a point of the latter sort.

There can be no doubt that the privilege of engaging in private practice has contributed enormously to the efficiency of the Indian Medical Service and to its popularity as a career; and, so far as we are aware, it has never been pretended that it has been abused to the detriment of the public service.

Anglo-Indians outside the medical service have always held most exaggerated ideas as to the emolu-

ments obtainable from the service, but still, twenty years ago, any civil surgeon might fairly expect to supplement his pay by £100 to £200 a year from this source, and in the larger stations his income might even equal that of a covenanted civilian of his own standing. All this, however, is a thing of the past, as far as the smaller stations are concerned, and is woefully diminished in the larger.

In each province there are some few stations which still retain some attractions from this point of view, but these are very properly the reward of prolonged good service, and, practically speaking, up to fifteen years' service or thereabouts, the less an officer expects to gain from this source the less will he be disappointed. There are various causes for this. In the first place, we have trained in our Indian universities large numbers of highly qualified native practitioners, whose habits of life enable them to charge fees much smaller than it would be either remunerative or fitting for an European officer to accept, and to this may be added the unavoidable unpopularity of all medical men trained on the European system, as the outcome of the efforts of the Indian Government to cope with plague. Owing to this a large proportion of patients who in old times would have consulted the civil surgeon or his assistants, according to their means, now resort to the *unani haqim* or Hindu baid, and it is only when these have failed and the sick man is past all human aid, that the European practitioner is called in, and when he is so, it is obvious can expect but scanty emolument or credit from the contingency.

All these adverse conditions might, however, be expected to yield to the personal influence of a really skilful and energetic officer, were it not for the needless way in which medical officers are harassed by constant changes of station. A remunerative private practice can no more be built up in a day or a month in India than in any other country, but an individual officer's tenure of any station rarely exceeds a year, and is often a matter of a few months only. An amiable desire on the part of the powers that be to treat their servants fairly is no doubt largely responsible for this, but to the victims of this misplaced affection the results are little short of ruinous. To account for how this comes about it is necessary to explain the plan on which the Civil Surgeon's official emoluments are calculated. The Government first docks fifty rupees from his military pay, and then compensates him by certain additional charges, the value of which varies in different stations. Thus the superintendentship of a district jail is paid from 50 to 150 rupees a month and in the majority of stations this is the only additional charge, but in other places there may be the medical charge of a railway, of a lunatic asylum, coolie department, remount establishment, &c. To give an example: in the Punjab, the Civil Surgeons of Simla and Murree draw 50 rupees per mensem less than their military pay, while those at Heshiapur and Gujrut find their position unaltered. Ludiana and Hirsar draw 25, Gujranwalla, Ferozepur and Delhi 50, and Multan 100 rupees more than their military pay. Now, in order to give all their share of these good things, it is customary when a senior goes on furlough or retires to institute a sort of game of general post, each officer stepping up into the next best place; but as the expenses of the move, for which he is allowed a fare, two first class fares swallow up one or two months of his entire pay, he is far from being a gainer by the change, and we would plead that greater consideration should be exercised in this respect, and that all unnecessary changes should be avoided, the more as they are even more undesirable from the official point of view than they are on private grounds, for local knowledge is of the first importance to the efficient conduct of a civil surgeon's duties.

Hitherto we have been considering the position of the ordinary civil surgeon, but in the political branch of the service the conditions are far worse, and are the outcome of deliberate efforts on the part of Government to reduce this source of income.

Indian noblemen are accustomed to regard it as only consonant with their position to reward handsomely their professional advisers, and generally the amount of the fee was left to the patient, though usually the sum tendered was only about what would be expected by a leading practitioner in England from a wealthy client. Some years ago, however, a native chief, choosing to consider that he owed his life to the exceptional skill of his medical attendant, presented the latter with the handsome fee of a lakh of rupees, or about £7,000. The gift, though princely, was, it must be remembered, entirely spontaneous, and astonished no one, probably, more than the recipient. The Indian Government, however, which had hitherto made no regulations on the subject, ordered the officer to refund the entire sum, but he preferred to send in his papers, and has since, by his talents and originality, attained a far better position in England than he could have ever expected to gain in India. Thereupon were instituted a series of orders on the subject, which have gradually been made much more stringent, till they are now so inquisitorial and humiliating that some officers prefer to refuse all remuneration rather than be subjected to the indignity involved in claiming a fairly earned reward.

Charges which would be regarded as reasonable in any part of England, and which have been passed as moderate by the medical administration are returned to the latter, it is said, with some insulting endorsement such as "perfectly monstrous," and officers have been left without any payment whatever, and punished for making charges based on the ordinary scale of fees customary in India. For example, the heir of a reigning chief was affected with a chronic tubercular bone affection. For over a year the Agency surgeon was in daily attendance, and often called up at night. He kept an account of his visits and charged the ordinary Indian fees, but the claim was rejected as excessive, and he was further punished by removal, not receiving a penny for his long and anxious attendance. The indignant chief, naturally considering himself dishonoured by the transaction, refused to call in the new Agency surgeon and resorted to a native haqim, who, of course, had no medical training whatever in the European sense, and this worthy really did charge in a style that might fairly be called monstrous—but as the haqim was a free agent the chief had to pay. The net result was gross injustice to the unfortunate medical officer, deprivation of proper medical treat-

ment to the patient, and an extortionate bill to his father, the chief. As a matter of fact it is practically most desirable that Agency surgeons should act as medical attendants to the chief when the latter desires it, for the friendly relations that necessarily result between him and a member of the Agency staff, are frequently of the greatest value in smoothing over difficulties, and everyone "in the know" is aware that it is quite common for the wholesome influence so gained by medical officers to "save a situation."

There is no good reason whatever why these humiliating regulations should not be entirely abrogated. No regulations could possibly prevent a really unscrupulous man from quietly accepting what he would be perfectly right in considering was honestly his due, and the mere fact that they suffice to prevent this is enough to show that the service is not made up of men of the sort, and that the rules are therefore quite needless. Further, they are resented by the chiefs even more acutely than by the medical officers, for they naturally argue that if they may not choose their own doctor, and honestly pay his bill, they are far less free agents than persons who have not the misfortune to be "ruling" chiefs.

As a rule no other qualified medical man is available, and the outcome is that they must either do without proper medical attendance, or be placed in a most disagreeable position of obligation to a man whose income is a mere bagatelle compared with their own.

Enough, however, has been said to show that the interference with private practice of this class is useless and needless, and that it is vexatious and humiliating to all concerned, and to none more than to the persons it is ostensibly designed to protect.

We should be the last to deny that the Indian Government has not only the right but the duty of maintaining the highest possible standard of professional honour in all branches of the service, and with human nature what it is, it is inevitable that cases should occur which call for the strictest disciplinary action.

Far from regarding such severity with disapproval the members of the service would be the first to applaud the prompt dismissal of an extortioner or blackmailer, but perhaps not the least extraordinary feature of the case is the reprehensible levity with which one or two such cases that have happened in the last twenty-five years have been dealt with. That such men should be given "another chance" is simply regarded as a blot to the fair pages of the nominal roll, in which the Indian Medical Officer justly feels the greatest pride.

No one denies that such cases will occur, and must be dealt with, but this is no defence for legislating for an honourable service, as if its members were a den of thieves, and as long as these rules are retained it is impossible for the Indian Medical Officer to feel that he is being treated not only as an officer, but also as a gentleman.

TUMOUR AND CANCER AMONG THE NATIVES OF ANGOLA.

Dr. F. Creighton-Wellman, Benguella, West Africa, in a communication to the American Society of Tropical Medicine, states that malignant tumours are uncommon amongst the natives of the district in which he is quartered. Of non-malignant tumours keloidal fibromata are by far the most numerous. The actual figures are:—Sarcoma, 2 cases in young women; multiple fibromata, 1 case; keloidal fibromata numerous; myxoma 1 case of nasal polypus; chondroma, 1 case; papilloma, warts, cutaneous horns, and bilharzial papillomata, rare; lipoma, several; hydrocele, not uncommon.

Dr. Wellman's experience extends over several years, and he has had the opportunity of examining many natives.

THE BIRTH-RATE IN THE PUNJAB.

Effect of Plague and Malaria.

The sanitary authorities in the Punjab state that the influence of plague on the birth-rate is of an indirect and general nature only; and that in spite of the fact that there were 334,897 deaths from plague in 1905, the birth-rate in the Punjab rose from 41·5 to 44·4 per thousand of the population. It is noticeable that more women than men die of plague in the Punjab, a fact probably owing to women being secluded indoors and therefore more in contact with the sources of infection. The birth-rate would seem to be lessened more markedly by the prevalence of malaria than of plague. A severe malarial outbreak in the autumn is reported to affect the birth-rate in the following year more than any other form of disease. For four years in succession the death-rate in the Punjab has been higher than the birth-rate; and the Punjab has recently had the highest death-rate of any district of India, amounting to no less than 47·55 per thousand.

PRIZES OFFERED FOR DISCOVERY OF THE TYPHUS FEVER GERM.

The Mexican Government have offered three prizes of $20,000 each for (1) the actual discovery of the typhus germ; (2) its mode of transmission to man; (3) and of a successful preventive or curative serum or effectual remedy. Communications to be addressed to the Secretary of the Academy, Dr. D. I. G. Cosio, Ortega 9, Mexico.

The reason for this liberal offer is that typhus is prevalent in a part of Mexico at the present time where, under the name of "tabardillo," the disease has attacked some 860 persons, of whom 185 have died. Dr. Terres, of Mexico, has published several facts in connection with the prevalence of typhus in Mexico. He states that the disease is not transmitted by direct contact; that it is seldom met with below an altitude of about 2,000 feet, whilst it is endemic in nearly every town above this altitude; the disease is especially prevalent during dry seasons.

Dr. Ignacio Prieto, of the National Pathologic Insti-

tute, Mexico, states he has isolated a streptococcus from the cerebro-spinal fluid of typhus patients, which he thinks may be the causal germ. It frequently appears as a diplococcus. Inoculation of animals has proved positive, the time of death varying according to the strength of the injection. There is said to be some difference in the clinical signs between the Mexican and the European type of typhus, in as much as the Mexican variety does not reach its maximum temperature for three or four days. Moreover, the temperature is first intermittent, then remittent, and finally becomes continuous in the Mexican variety.

Notes and News.

MOSQUITO BITES.—Schill, in the *Schweizer Woch. für Chemie und Pharmacie*, advises applying a paste or saturated solution of bicarbonate of sodium to the bitten part. Thymol, 50 per cent. alcoholic solution, applied to hands, neck and face, is effective in keeping off mosquitoes.

EUROPEAN AND AMERICAN AILMENTS.—At one time gout, glycosuria and multiple sclerosis, were regarded as rare diseases in the United States of America, and in text-books the rarity was insisted upon. Whether the people of the United States were really less seldom afflicted with any one of these troubles than were the European parent stock, is a matter of opinion. At the present time, however, the several ailments mentioned are as prevalent in one Continent as in the other.

AN INGENIOUS MOSQUITO DESTROYER.—Professor Blanchard showed at a recent meeting of the Académie de Médecine, Paris, an invention by M. Chaulin, devised to destroy mosquitoes. The apparatus consists of a small metal cage within which is an electric light. The cage is connected with a battery whereby an alternating current is made to traverse the wires of the cage. The mosquito is attracted by the light to settle on the wires and is promptly electrocuted.

MISS R. A. BETTY, Senior Lady Superintendent of Queen Alexandra's Nursing Service for India, has been decorated by His Majesty King Edward with the Royal Red Cross, in recognition of her services in India.

ST. HELENA.—According to the official report for 1905, measles appeared in March, 1905, and up to August 28th, 1905, when the last case occurred, no fewer than 500 persons were attacked. Seeing that the total population of the island amounts to only 3,761, it would appear that almost one-seventh of the inhabitants contracted the disease. No one died of the disease except one person, aged 52, who was also the subject of malignant disease. It is sixteen years since measles visited St. Helena, so that the low death-rate is rather remarkable.

ENTERIC IN INDIA. — STANDING COMMITTEE APPOINTED.—The Government of India have sanctioned the formation of a Standing Committee for the purpose of investigating and advising on enteric fever in India and its prophylaxis. The first meeting was held at Simla on July 31st in the United Service Institute.

The undermentioned officers, nominated by the Commander-in-Chief, have been appointed on the Committee:—President: Surgeon-General Gubbins, P.M.O., His Majesty's Forces in India; Vice-President: Surgeon General Scott Reid, P.M.O., Northern Command; Members: Colonel Forman, P.M.O., Bombay Brigade; Lieutenant-Colonel T. P. Woodhouse, Captains L. W. Harrison, E. B. Knox (secretary), A. B. Smallman and Lieutenant Luxmoore, Royal Army Medical Corps. Nominated by the Home Department — Members: Lieutenant-Colonel Leslie, Sanitary Commissioner with the Government; Lieutenant-Colonel Semple, Director of the Central Research Institute; Major G. Lamb and Captain Greig, I.M.S.

A SMART shock of earthquake was felt at Simla and at Naggar (Kangra District) on July 21st, and slighter shocks at Lahore and Dalhousie.

INFECTIOUS DISEASES HOSPITAL AT COLOMBO, CEYLON. — News has been received that a lady travelling home with her children from Calcutta had a most unhappy experience at Colombo recently. One of the children developed small-pox at sea, and on arrival at Colombo, the family were taken to the infectious diseases hospital. Instead of finding a properly equipped hospital, Mrs. Craig and her children found a shanty with a couple of untrained Cingalese in attendance. The isolation rules prevented the mother from seeing her sick child, and the attendants were altogether unfitted to look after an European child of three years. The child died, and when the whole of the facts of the case were made known by Mr. W. J. Craig, who had been summoned to Colombo by his wife, the indignation aroused was general. Sir Henry Blake, the Governor, made a private surprise visit to the infectious diseases hospital and declared it to be a disgrace to the Colony. A site for a new hospital has since been decided on. —*Times of India*, July 28th, 1906.

THE annual (1905) report on vaccination in Burma states that: "Out of a population of 10,500,000 the total number vaccinated were 500,000. Two hundred vaccinators were employed; the cost of the work amounted to 114,000 rupees."

WE have to hand the current "Special Plague Number" of the *Indian Medical Gazette*, which should be obtained by all interested in the subject, as, for the most part, the papers included in it are of a high standard of excellence and are, moreover, of a most practical character. Perhaps the most noteworthy point is the fact that almost without exception, Captain Glen Liston's rat-flea theory of the etiology of plague is accepted as substantially proved; and such being the case we are obviously within measurable distance of a really practical and practicable plague policy for India. There are many Hindu

sects that would have some objection to the killing of rats, and who might, at any rate, refuse to assist in such operations, but except the Jains, who, like Gilbert's Koko in the Mikado, "can't kill anything," few would have any scruples as to the slaughter of fleas, so that the use of insecticides is not likely to rouse opposition. That the contributions should not be of uniform merit is only natural, and in one case it is certainly difficult to understand how the author persuaded himself that he had anything original to communicate. This paper is rendered all the more irritating by its slipshod English.

Here, no doubt, we have the keynote to the title selected for this paper, and it is one which cannot fail to be of very great interest to all medical officers in this country, and in particular to those engaged in efforts to subdue it.

This is a complete paragraph, and if anyone can say to what substantive the final "it" stands pronoun their powers of analysis must far exceed the average. Does the "it" refer to the "keynote," the paper, or the country? In view of such a gem of construction, one is left in doubt whether mere carelessness or ignorance has led the author to speak of *Pulex cheopis*, Rothschild, as "the" rat-flea. As rats commonly harbour several species of *Pulicidæ* no one of them can fairly be called "the" rat-flea; but if any flea has a right to the title, it is *Ceratophyllus fasciatus*, which is found on rats all over the world, whereas *P. cheopis* has only once been recorded in temperate climates, and—if so spoken of at all—would probably be better called "the jerboa flea." As, however, most fleas will attack a variety of hosts, it is misleading to speak of any of them as appertaining to any particular animal. After all this, it is not surprising to find that the writer regards the *de novo* origin of bacteria as possible, albeit not proven. Not the least valuable portion of this excellent number are the able series of editorial comments which together form a most handy commentary of our present knowledge of this most difficult subject.

Major J. Chaytor White, I.M.S., at present on leave in England, has been deputed by the Government of India to visit a number of Municipalities in England, with the view of studying the working of recent sanitary improvements.

Captain James, I.M.S., in an interesting report, discusses the old idea that Kala-azar has any relationship with malarial fever, and appears extremely sceptical as to the so-called disease having any connection with the Leishman-Donovan parasite. It is interesting to note that the Government entomologist has found in Assam a "near ally of the tsetse fly," and suggests that it may have some connection with the disease. The *Indian Pioneer* very pertinently remarks: "If the scientific authorities do not hurry up the disease may have died out before its origin is discovered, for it is certainly decreasing steadily in virulence. In 1897 some 18,597 deaths were reported in Assam as due to Kala-azar; last year there were only 3,030." And in favour of Captain James' views it may be noted that there is no evidence of any coincident decrease, either of malaria or of the Leishman-Donovan parasitic disease, though in the latter case too little is known as to the diffusion of the malady to render any conclusions practicable.

The death rate from cholera in Eastern Bengal and Assam was last year more than double that of the preceding decade. In Dacca city the Civil Surgeon effectually stamped out the disease by prompt treatment of all tanks and wells with permanganate of potash. One is tempted to ask why this measure was not employed elsewhere; but we are aware that it is not always possible to carry out sanitary measures as could be wished in India; and the reason, in the present instance, is probably to be found in the political unrest which has attended the establishment of the new province. Dacca, however, is a great Mahomedan centre, and it is noteworthy that the members of this community, though sometimes accused of backwardness, are often less difficult to deal with in sanitary matters than their Hindu fellow-countrymen.

Personal Notes.

Indian Medical Services.

Arrivals Reported in London.—Major W. J. Buchanan, Major J. B. Jameson, Col. H. K. McKay, Captain J. C. A. Kunhardt.

Extensions of Leave.—Lieutenant-Colonel P. D. Pank, 2 d. furlough; G. F. T. Harkness, 3 m., medical certificate.

Permitted to Return to Duty.—Lieutenant-Colonel P. D. Pank, Captain T. H. Symons, Surgeon-General W. R. Browne, C.I.E.

Postings.

Lieutenant Steel officiates as Assistant-Director, Bacteriological Laboratory, Bombay.

Captain R. F. Baird officiates as Civil Surgeon, Farrukhabad.

Dr. H. A. Macleod, Civil Surgeon (uncovenanted service) from Saharanpur to Mugaffanagar.

Captain U. S. J. Shaw officiates as Superintendent Royal Lunatic Asylum.

Lieutenant-Colonel Harrington officiates as Chief Medical Officer, Rajputana.

Major P. Haig, Residency Surgeon, West Rajputana States, to the additional charge of the Agency, Jodhpur.

Captain H. Mackenzie, services temporarily lent to Government, Punjab.

Lieutenant C. Henderson, 29th Lancers, to Burmah Military Police.

Major W. Vost to be Civil Surgeon, Gorakhpur.

Leave.

Major W. R. Clark, Civil Surgeon, Umballa, combined leave, 2 y.

Retirements.

Lieutenant-Colonel J. Maitland, Madras.

Senior Assistant Surgeon Captain Staggs, I.S.M.D.

List of I.M. Officers in Military Employ, on Furlough.

Abbot, Captain S. H. L., 12 m., May 4th, 1906.
Anderson, Captain D.N.
Babington, Lieutenant J. W. H., 1 y., September 27th, 1905.
Baker, Captain D. G. R. S., 8 m., May 16th, 1906.
Bradley, Captain R. J., 8 m., April 2nd, 1906.
Brown, Captain H. R., 18 m., April 15th, 1905.
Buchanan, Major W. J.
Collinson, Captain W. J., 1 y, June 9th, 1906.
Cruddas, Captain H. M., 1 y., March 13th, 1906.
Earle, Major H. M., 1 y., April 29th, 1906.
Eyre, Lieutenant-Colonel, M.S., 18 m., September 23rd, 1905.
Fooks, Lieutenant-Colonel H., 19 m., March 28th, 1905.

Gilbert, Major C. E. L.
Graham, Captain J. D., 1 y., April 16th, 1906.
Groube, Captain G. P. T., 1 y., April 14th, 1906.
Hagger, Captain R. L., 8 m., February 16th, 1906.
Hamilton, Captain W. G., 17 m., October 5th, 1905.
Hamilton, Colonel H., C.B., 6 m. 18 d., April 28th, 1906.
Harkness, Lieutenant G. F. L., 9 m., February 15th, 1906.
Harriss, Major S. A., 6 m., May 6th, 1906.
Illius, Captain H. W., 1 y., March 19th, 1906.
Johnson, Major C. A.
Kirkpatrick, Captain H.
Kunhardt, Captain J. G. G.
Lee, Lieutenant-Colonel W. A.
Lister, Captain A. E. J., 21 m., February 12th, 1905.
MacKelvie, Captain M., 12 m., October 15th, 1905.
MacRae, Colonel R., 7 m., May 4th, 1906.
Maidment, Major F. G., 1 y., March 21st, 1906.
Marr, Captain C. F., 1 y., April 24th, 1906.
Mason, Captain W. G., I.S.M.D.
Meakin, Captain H. B., 18 m., March 23rd, 1905.
Murphy, Captain A., 8 m., June 6th, 1906.
Parker, Captain C. S., 18 m., August 28th, 1905.
Pinchard, Captain M. B., 18 m., August 12th, 1905.
Pratt, Lieutenant-Colonel H. J.
Pridham, Captain A. T., 7 m., March 18th, 1906.
Reynolds, Captain L., 9 m., March 4th, 1906.
Rodgers, Lieutenant-Colonel J. W., 52nd Sikhs, 1 y., January 26th, 1906.
Russell, Major A. R. P.
Sarkies, Lieutenant-Colonel C. J., 290 d., April 19th, 1906.
Stephen, Captain J. P., 1 y., June 24th, 1905.
Swaine, Lieutenant-Colonel C. L.
Tate, Captain G., 1 y., October 3rd, 1905.
Thompson, Captain F. T., 54th Sikhs.
Tuke, Captain A. W., 9 m., May 1st, 1906.
Turner, Major R. G.
Whale, Captain H., 8 m., June 5th, 1906.
Wilcocks, Captain R. D., 17 m., May 27th, 1905.
Younan, Lieutenant-Colonel A. C., 1 y., March 1st, 1906.
Youngerman, Lieutenant-Colonel E. P., 1 y., March 2nd, 1906.

INSPECTION OF ALLEN AND HANBURY'S WORKS AT WARE, HERTFORDSHIRE.

THE admirable way in which the arrangements for the representatives of the press on their recent visit to Messrs. Allen and Hanbury's factories at Ware, Herts, were carried out convinced the visitors, even before they left by special train from Liverpool Street, that a capable and enterprising spirit must be at the head of affairs, and that something out of the ordinary was in store for them. Those anticipations were more than realised, and a thorough inspection of the works and minute examination of the many ingredients employed in the manufacture of the firm's numerous capsules, lozenges, &c., and the celebrated Infants' Food, could leave no doubt that everything was of the finest and purest quality, and the processes of transforming the raw materials into the desired results were carried out under the best of sanitary conditions. The factories stand in their own grounds, comprising some acres of grazing land, occupied by a large herd of cows whose milk is used in a variety of Messrs. Allen and Hanbury's products. In these days of scares by potted and tinned foods it is always as well to do what one can to remove biassed impressions, and so far as Messrs. Allen and Hanbury's packing and the supervision exercised in hermetically sealing and keeping air-tight their delicacies and preventatives of, and remedies for sundry, ills are concerned, it is only right to say they could not be surpassed, and consequently a minimum of damage is likely to be caused to them by climatic influences.

CHELTENHAM.

THE OPENING OF THE NEW SPA.

FOR those who have spent the active part of their lives in warm countries, and as a place of education for their families there is no more desirable and popular town to reside in than Cheltenham. The education for children is excellent, both for boys and girls, and within the means of all. In former times Cheltenham was famous for its mineral waters, but of late years the reputation of the town as a place of "cure" has been unaccountably and most unjustifiably neglected. It is satisfactory, however, to know that as a place of "cure" the Cheltenham authorities have taken a step in advance, and the opening of the new Spa cannot fail to prove an attraction to many. Just now "Garden Cities" are much talked about in England as if they were something new, but we have in Cheltenham one of the finest garden cities, not only in England, but in Europe. Being an old-established resort, it is without the drawback of the much vaunted modern imitations. The *Journal of the Royal Institute of Public Health* remarks:—"It would be difficult to exaggerate the advantages of the place from the point of view of residence. It is well situated, the shops are admirable, and the means of amusement greater than at most English health resorts. The climate of Cheltenham is of a distinctly sedative type. The humidity is considerable, making the conditions particularly equable. It is, like most of our western and south-western stations, admirably, or rather pre-eminently, suited to the very old and the very young. For those who have done their life's work, especially in some tropical climate, such as India, there is no better place in Europe than Cheltenham. All this has been long recognised, and one has only to go to Cheltenham and make acquaintance with its inhabitants, to realise that the population is largely made up of people who have been abroad and those who have children to educate.

"From the spa point of view, the waters are comparable to those of Brides-les-Bains, St. Gervais, Homburg, Kissingen, and others, which contain chiefly the chloride of sodium and the sulphate either of sodium or magnesium, or both. Inasmuch as it constitutes the only drinking-water spa of this type in England, and, judging by the spirit which now seems to animate its authorities, it certainly ought to have a great future before it.

"Of the New Central Spa, which the Corporation of Cheltenham has recently established in the Town Hall, we may say at once that any town which is capable of building a Town Hall such as that which now graces Cheltenham, ought to be capable of anything in the way of enterprise to render the town successful and attractive from the health resort point of view. It would be difficult to imagine anything, even at Continental stations, more suited to the requirements of a health resort than the magnificent

building in which the Central Spa is now situated. It is, in fact, a casino of splendid dimensions, admirably designed and tastefully decorated.

"Cheltenham has this peculiarity, that its climate is essentially a winter climate, and there is no health resort presenting the same type of waters to which patients can be sent in the winter. This is an advantage of which the authorities would do well to make full use."

Recent and Current Literature.

A tabulated list of recent publications and articles bearing on tropical diseases is given below. To readers interested in any branch of tropical literature mentioned in these lists the Editors of the JOURNAL OF TROPICAL MEDICINE *will be pleased, when possible, to send, on application, the medical journals in which the articles appear.*

The "Indian Medicine Gazette," Special Plague Number, July, 1906.

(1) THE SPREAD OF PLAGUE.

Browning-Smith, S., Major I.M.S., from experiences gained in the Punjab, is of opinion that in the spread of plague (1) the rat is the principal disseminator; (2) that the rat is a necessary factor for epidemic bubonic plague; (3) flea prevalence is also necessary; (4) a plague epidemic will end with the disappearance of either the rat or the flea; (5) seasonal variations of plague depend on flea prevalence, the habits of man and the breeding of fresh generations of rats.

(2) THE NATURAL HISTORY OF PLAGUE.

Stevens, A. F., Capt. I.M.S., draws special attention to the disseminating agencies of plague and classifies them into: (1) Universal or territorial dissemination, mostly by travellers, merchandise, parcels and correspondence and by animals; (2) regional dissemination by contiguous (urban) and local (rural) dissemination; rats and rat-destruction sums up the whole subject of the spread of plague and the means we have of combating the disease.

(3) HOW PLAGUE IS SPREAD.

Gordon Tucker, E. F., Capt. I.M.S., suggests practical palliative measures for municipal authorities to carry out when brought face to face with an epidemic of plague. They are chiefly erection of temporary dwellings in open spaces near evacuated houses for the poor, and outside the city for the richer classes. Disinfection of infected houses where a family accepts inoculation. Special laws to ensure good rat-proof dwellings for stables and granaries. Destruction of rats.

(4) PLAGUE IN THE CITY OF MADRAS.

Ross, T. S., Capt.. I.M.S., states that until January 20, 1906, indigenous plague was unknown. A few sporadic cases developed in different parts of the city, but although rats were found infected the disease never became generally prevalent. Some attribute the extraordinary exemption of anything like an epidemic of plague in Madras during all the ten years the disease has prevailed in India, to the absence of the *Mus decumanus*. The *Mus Rattus* and the *Nescocia bandicota* are met with, but the former is a non-burrowing animal and therefore does not pass from house to house freely for fear of being caught by the Bandicoot; in this way the Bandicoot has come to be regarded by some people as the means by which plague has been kept out of the city.

(5) HOW DOES PLAGUE SPREAD?

Elliott, Alex. M., M.B., mentions, amongst the several known means of spread, that cats are probable carriers of infection, and that from fleas taken off plague-infected cats, plague bacilli may be obtained. An interesting case is the probable infection of a man in India who picked up a dead rat dropped by a vulture; the fact that the buboes proved to be axillary in this patient is also suggestive and instructive.

(6) THE EFFECTS OF RAT EXTERMINATION ON THE INCIDENCE OF PLAGUE IN A SELECTED AREA IN AZAMGARH CITY.

Walker, J. W., Capt. I.M.S., draws special attention to the fact that plague epidemics, in smaller towns at all events, seem to be particularly severe in alternate years. The experiment of killing rats and mice by baits consisting of bread sprinkled with the "Common Sense Rat Exterminator" was carried out in the south-eastern district of Azamgarh. The result when the epidemic of plague visited the city was satisfactory, in as much as thirty-two cases were recorded against 133 in the north-eastern quarter, where no steps against rats had been taken and where the people lived under much the same conditions. A point observed in the rat-free area was that cases imported thither do not give rise to the series of infection to be seen in places where rats abound. The investigation was carefully and scientifically carried out.

(7) HOW PLAGUE IS SPREAD.

Allchen Gill, C., Lieutenant I.M.S., is of opinion that the part played by man in the spread of plague is of equal importance to the *rôle* of the rat. A plague epidemic in any place is usually preceded or accompanied by a mortality among rats, but if this is inquired into, in most cases it will be clear that the rat infection has taken place from man. The rat-flea *Pulex cheopis*, is evidently the chief intermediary host between rat and man, but whether as a mere transmitter or as an animal in which the bacillus of plague passes through an evolutionary stage, is unknown.

(8) AN EXPERIMENTAL INVESTIGATION AS TO THE POTENCY OF VARIOUS DISINFECTANTS AGAINST RAT-FLEAS.

Hossack, W. M. C., M.D., of the Plague Department, Calcutta, contributes a very interesting paper on the subject of rat-fleas and their destruction. He draws attention to the difficulty of being certain that the fleas have completely disappeared from the rat fur, even after careful search. He also shows that fleas, after being immersed for a time in fluid disinfectants, may promptly recover when allowed to escape from the liquid, even after many minutes of immersion. He finds phenyl 1-500 (roughly two tablespoonfuls to a bucket of water) is an excellent pulicide, paralysing the flea in a few seconds and killing it in about one minute. Izal, cyllin and crude phenyl are equally efficacious, but the perchloride of mercury, even in strong solution, 1-250, was disappointing. He advises giving up perchloride of mercury solution, which is in common use in India, in favour of one of the others mentioned. It must be remembered, however, that phenyl, izal, &c., has little power as a germicide against plague, and as Dr. Hossack remarks the substance that will give the best results as a pulicide and germicide has yet to be determined.

(9) RAT-KILLING FOR PREVENTION OF PLAGUE.

King, G., Captain, I.M.S., mentions several varieties of rats met with in Bihar and adjacent districts of India.

(*a*) *Field Rats.*—(1) *Gerbillus Indicus*, locally named "Hurna" (the Indian antelope or Jerboa rat), a field rat; (2) *Mus Mettada*, locally named "Kuroch," probably a large northern variety of the soft-furred field rat of S. India; (3) a field rat resembling the "Kuroch" rat, termed locally "Churhowa," but which Captain King cannot classify; (4) the *Nesokia Bengalensis* (the Indian mole rat); (5) the *Nesokia Bundicota* (the Bandicoot), termed locally "Ghous," the pig-rat. Of these field rats, 1, 2 and 3 do not burrow in outhouses; 4 and 5 are rare in Bihar and do not burrow in outhouses.

(*b*) *The House Rats.*—(1) *Mus Rufescens*, termed locally,

"Gach Kachuha," lives in trees, roofs of houses and holes in mud, walls, &c.; (2) *Mus Alexandrinus*. These rats are closely related in habits and in the fact that the tails of both are distinctly black, distinguishing them from all other rats. The importance of this feature is apparent when it is known that these two species are the transmitters of plague, and that when the extermination of rats is determined upon, it is the tails of the black rats that should alone be paid for, as rats with yellowish tails or black with yellowish fur over joints are innocuous, so far as plague is concerned. It would appear that the "*Mus Alexandrinus* is really the eastern variety of the European black rat, *Mus rattus*, which was abundant in Europe from 1347 to 1680, but is rare now, having been ousted by the brown (drain and cellar) rat, and by better housing and sanitation since the great plague epidemics in Europe between the above dates."

"Centralbl. f. Bakten," I. Orig., T. xl., p. 630.

THE ACTION OF *Aspergillus niger* AND *glaucus* ON CULICID LARVÆ.

Galli-Valerio, Bruno, and Rochazdi Jongh, J. The larvæ were placed in crystalising glasses, flasks, and casks of water, and sporulating cultures of the above species added. In the smaller vessels, the greater part of the culicids failed to survive the larval stage and only half the pupæ reached the adult condition. In the larger vessels the mortality was less severe, and the authors conclude that though in the natural state the larvæ may become infected, the method cannot be recommended as a practical measure, as the destruction dealt by either petrol or saprol is much more rapid and certain.

"Thomson Yates and Johnston Laboratory Reports," T. vi., Part 2, p. 139.

THE HABITS OF THE MARINE MOSQUITO (*Acartomyia Zammitii*).

Theobald, F. V., premises that there is little doubt that Malta fever is conveyed either by the above mosquito or by the biting fly *Stomoxys calcitrans*.

This mosquito is found throughout the Mediterranean littoral and is exceptional in passing its larval and pupal stages in salt marshes of a concentration of 48 to 87 grammes per litre. Should the salt commence to crystalise out the larvæ must either emigrate or die. Interesting details are afforded of the larval and adult life history of the insect. It may be remembered that Sergent has described from Algeria *Grubhamia mariæ*, a closely allied form, which also passes its larval stage in strongly saline salt marshes.

"C.R. Acad. Sciences," T. cxlii., p. 260.

THE ANATOMY AND HISTOLOGY OF THE IXODES.

Bonet, A.—A short study of the eye and poison glands of these arthropods. The poison glands consist of large pyriform cells, placed among the alveoli of the salivary glands, and distinguishable by their staining in acid solutions. They are more numerous in *Argas* than in *Ixodes*, which explains the greater irritation produced by the bites of the former genus. Their secretory activity is associated with nuclear emissions of the same character as the venin granules of other arthropods and of the ophidia.

It may be noted that the poison glands of mosquitoes also consist of similar voluminous pyriform cells.

"Scientific Memoirs of the Med. and Sanitary Departments of the Government of India."

THE ANATOMY AND HISTOLOGY OF TICKS.

Christophers, Captain S. R., concerns himself principally with *Rhipicephalus annulatus* and *Ornithodorus savignyi*, the latter being probably the camel tick, which Palton noted as also attacking man at Aden. A very complete account is given, with ample indications as to methods of examination, and in the last chapter some information is given on the structure of the egg and the embryology of the group. It is important to note that it is stated that the larvæ of *Ornithodorus* do not bite, whereas those of the *Ixodidæ* do.

"C.R. Acad. Sciences," T. cxlii., p. 1225.

THE EVOLUTION OF THE GYMNOSPOROUS GREGARINES OF CRUSTACEANS.

Leger, L. and Dubosq, O., revive Frenzel's hypothesis that certain gregarines parasitic in crustaceans, for which the latter instituted the genus *Aggregata*, have a double life history, and that the alternative host should be looked for among animals that prey largely on crustaceans, such as the cephalopods, and have submitted the question to experimental demonstration. They have never found the spores of *Eucoccidium*, from the intestines of cephalopods, open in the intestines of these molluscs, although they do so readily in the intestines of a variety of species of crabs, and the sporozoites when set free are actively mobile, and penetrate the epithelial cells of the crabs very readily. The greater part of them are stopped by the basal membrane, and undergo degeneration, but those that succeed in passing through it reach the peri-intestinal lymphoid tissue and grow into large young gregarines with a spherical nucleus and large karyosome, though many are in the meantime destroyed by the phagocytes. These stages agree with those already described by the authors in crabs naturally infected with *Aggregata vagans*, and they are led to believe that these intestinal gregarines of crabs have no connection with the cœlomic *Aggregata*, but there is reason to believe that they require an alternate host.

They further believe that *Aggregata* is the schizogonic and *Eucoccidium* the sporozonic stage of the same gregarine.

"Journal of Mental Science," April, 1906.

Knobel, W. B., Dr., discussing asylum dysentery in England, points out (1) that between acute inflammatory conditions of the colon and lesions of nerve cells and fibres of spinal cord, ganglia and atrophy of cerebral gyri, there is a distinct association. (2) Trophic influence is evidently impaired in insanity, hence the special susceptibility of the insane to dysentery. (3) The 'privy atmosphere' with which we are familiar in asylum wards may be due to this trophic impairment, and the air in the ward may be a factor in the spread of the complaint. (4) Many microbes, either singly or in mixed infection, may produce dysentery under certain circumstances. (5) It may be that dysentery is produced by some microbe normally present in the intestine becoming pathogenic, when the normal nerve stimulus is withheld. (6) It is significant that disturbance of the subsoil in the immediate vicinity of an insane asylum is apt to be followed by an outbreak of dysentery.

Notices to Correspondents.

1.—Manuscripts sent in cannot be returned.

2.—As our contributors are for the most part resident abroad, proofs will not be submitted to those dwelling outside the United Kingdom, unless specially desired and arranged for.

3.—To ensure accuracy in printing it is specially requested that all communications should be written clearly.

4.—Authors desiring reprints of their communications to the JOURNAL OF TROPICAL MEDICINE should communicate with the Publishers.

5.—Correspondents should look for replies under the heading "ANSWERS TO CORRESPONDENTS."

Original Communications.

SPRUE AND CHRONIC INTESTINAL LESIONS.

I.—THE DIET IN SPRUE—MEAT—MILK—FAST DAYS—WHY FAST DAYS ARE NECESSARY—SEA WATER FOR RECTAL INJECTIONS.

II. — SIGMOIDO-RECTAL STRICTURE A CAUSE OF CHRONIC INTESTINAL FLUX — A SIGMOIDO-RECTAL PYLORUS—THE USE OF THE SIGMOIDOSCOPE.

By James Cantlie, M.B., F.R.C.S.

I.

Opinions concerning the milk *versus* the meat diet of sprue, and of other lesions associated with intestinal flux, still afford material for debate. The majority favour the treatment consisting of milk only, a few favour a rigid *régime* of meat or of meat juices, whilst a third group temporise with a modification of the two extremes, and give a hesitating adherence to each. The writer has for years advocated and practised a rigid "meat" diet in sprue, and experience has tended to confirm the efficacy of the plan.

Meat Diet.

Whilst still adhering to the meat treatment as *the* means of curing sprue rapidly and efficiently, an extended experience has served to modify the sweeping assertion that by this means alone sprue is always permanently cured. The reasons for this belief are stated below. That a patient in what under ordinary circumstances appears the last stages of the illness, that is, when, in addition to emaciation, anæmia, dropsical effusion, &c, there is a decided rise in temperature, can be saved by putting the patient on home-made beef tea, raw meat juice and beef jelly, administered in teaspoonful doses every ten minutes if need be, the writer has proved again and again. A rise in temperature takes place in most cases of sprue some two to four weeks before what seems inevitable death, in sprue. Milk in such cases means death, and by meat juices alone can a patient, in what seems the last stages of the illness, be saved.

The further treatment in such serious cases will be found to be that as the patient's strength improves, which it will do, the time of feeding may, after the first twenty-four hours, be lengthened to every twenty minutes on the second day, and to half hourly or hourly feeds by the third or fourth days. By the fifth day, pounded beef (from top of round) will be tolerated and enjoyed, and the diet intervals may be increased to two-hourly feeds; pounded beef, meat juice, beef tea, and beef jelly being taken *seriatim* at the intervals mentioned. In a week or a fortnight, if the cure advances satisfactorily, vegetables, bread and stewed fruit may be added with benefit. At this stage, or it may be later, a relapse usually occurs, and meat seems to have failed and the doctor and patient are disappointed. This contingency is almost inevitable, and the doctor reverts to milk, or the patient seeks other advice. This is the critical period of the treatment, and one that causes anxiety and trouble. The solution of this difficulty is the object of this communication.

Milk Treatment.

This is so well known that it is unnecessary to describe it. It is the least troublesome to administer, it brings about, except in late stages of sprue, solid stools, and, the diarrhœa being in abeyance, the patient is satisfied with the result. Withal, however, it does not, as a rule, cure. A sprue patient can only be said to be cured when he can revert to a mixed diet, and it is at the period when other substances are added to the diet, be they starchy or nitrogenous, that a relapse is apt to occur and the patient and doctor are disheartened and disappointed. The solid stool produced by a rigid milk diet is not fæcal; it consists of a mass of agglutinated milk curd from which the whey has been extracted, and on the whey alone the patient has lived, and, it may be, improved.

Can the milk and meat diets be combined? In the ordinary sense, No! Meat cannot be digested when milk or milky substances such as milk puddings are given at the same meal. In ordinary day life it is the custom to take a milk pudding after consuming fish, fowl, or butcher's meat, and on the other hand milk is often drunk at meals along with meat in place of beer, or wine, or water. Such a combination is physiologically wrong. The old Jewish law that milk is not to be taken until at least two hours after eating flesh holds good for all time, and cannot be contravened with impunity by healthy people, and therefore far less so in patients with gastro-intestinal disturbances. How then can a milk and meat diet be combined if both are useful in sprue. Not by taking the two together; not even by taking the two at separate meals but on separate days.

Fast Days.

The patient on a meat diet should, say, every third or fourth day, fast from meat of every kind, and take milk, and milk only, for twenty-four hours. The writer has found this to be the secret of success in the prolonged treatment of sprue. Meat diet is almost certain to be attended by relapses; milk diet when modified is almost assuredly attended by recurrences of diarrhœa, and the ordinary attempts at a combined diet are equally productive of failure; but a rigid milk diet alternating with a varied diet on separate days will seldom fail.

Why Fast Days are Necessary.

The writer has practised the "fast from meat" plan with success for some time, but could not frame an explanation until he read a paper by Sir Lauder Brunton on the effects of a rigid diet. In the paper and in conversations with Sir Lauder Brunton on the subject, the writer has come to firmly believe in his explanation of the good effects produced by meat fasts in cases of intestinal flux. Sir Lauder puts it shortly thus: The bacteria of the intestine can accommodate themselves to almost any food; if a milk diet has been persisted in, the sudden change to a purely meat diet places the bacteria, accustomed to deal with

milk only, at a disadvantage, they cease to be active and largely die out, and their pathogenic properties are annulled. If, again, the meat diet is persisted in the bacteria recover, and again multiplying become virulent, and show their pathogenic effects as pronouncedly as before. Change this suddenly and completely by again reverting to, say, milk, and the bacteria are once again hampered or largely killed; in time they become accustomed to the altered media of their environment and again become pathogenic. Whether this be the true explanation or not it fits in with clinical facts, and the writer has adopted it with success as a rational basis of treatment. Be the nature and cause of sprue what it may, a bacterial infection, a fermentation, or a mere physiological perversion, the explanation offered is justified, both scientifically and clinically. A change of diet, as of air, or of water, seems necessary to human welfare. In Britain we go for a change of air, in China it is said to be for a change of water that the invalid goes, and it is held by many that a "city" dinner is an excellent hygienic factor in the digestive economy. Change of "air" is not confined to man's requirements; animals, and more especially birds, find it necessary, although it may be for different reasons; and all animals in a natural state change their lairs or environment from time to time. The scientific explanation of this is probably based on hygienic factors, and would bear closer investigation with benefit. Sameness of diet is apt to lead to "staleness" of body and mind, a fact which it would be well also to probe more deeply. Advocacy of "fast days" from the stereotyped diet in sprue, therefore, is no heterodox innovation, but one which but fulfils natural and therefore normal bodily requirements.

Several sprue cases, by the advice of the writer, have returned to the Tropics and follow the fast day *régime*. One day in the week the usual diet of meat, vegetables, fruit, &c., is given up, and the patient takes nothing but milk for twenty-four hours. In this way several persons for whom life in a warm climate would have been otherwise impossible, are to-day enjoying good health. One usually allots Sunday as the milk day, but there is no reason why the "fast" day from meat should not be Friday, as it used to be with us, and is still in Catholic countries. Whichever day is chosen, however, is a matter of domestic convenience, but the omission, in cases of sprue, is apt to lead to recurrence of the ailment.

Sea-water for Rectal Injections.

The writer finds that of all forms of lavage for the bowel sea-water is the best. In chronic dysentery, in mucous colitis, in ulcerative colitis and even in sprue injections of sea water—a couple of pints filtered, warmed, but not diluted—are highly beneficial. The injections may be given daily for three days, but afterwards every third day or once a week, until all mucous or fermentation is removed. The same good is not obtainable by "sea-salt" dissolved in water, although sea salt thus used is perhaps better than any other of the vegetable decoctions or mineral solutions in common use.

II. — Sigmoido-Rectal Stricture — A Sigmoido-Rectal Pylorus—The Use of the Sigmoidoscope.

The writer has during recent years made it a rule to examine the rectum of all cases of intestinal flux. To merely call it rectal examination is misleading, for, as a rule, the rectum by digital examination or by the ordinary rectal speculum will be found normal. The trouble in three-fourths of cases of chronic diarrhœa, dysentery, mucous colitis will be found at the junction of the sigmoid flexure and rectum six to eight inches up, that is, eight inches from the anus anatomically owing to rectal curves, but only six inches when straightened by the sigmoidoscope. At this point, there is naturally a narrowing of the bowel, even a pylorus with some of the functions of the gastro-duodenal pylorus. We are accustomed to think of *the* pylorus as if in some way the name meant an anatomical attribute of the stomach, but the word pylorus has no such signification. Pylorus is derived from the Greek words πυλη = gate and ουρος = guard—a guard of the gate; the gate may be at the stomach, or sigmoid, or anywhere else. Therefore, to term the narrow junction of the sigmoid and rectum the sigmoido-rectal pylorus is no misnomer. The anatomy and physiology of this sigmoido-rectal pylorus, moreover, resembles in many ways the gastro-duodenal pylorus, a point which the writer will deal with more fully in the near future. It is no mere narrowing, but a true guard of the gateway from the sigmoid to the rectum. In chronic dysentery and in cases of colitis, this point will be found tender to palpation from the surface of the abdomen, at a point on the left side almost corresponding with McBurney's point on the right side in cases of appendicitis. Examination of the bowel at this point by the sigmoidoscope will elicit tenderness, at times exquisite; the mere touching of the point with a piece of cotton wool in a holder introduced through the sigmoidoscope will, as a rule, cause the cotton wool to be blood-stained, and the introduction of a long tube, say an œsophageal tube, through the bowel at this part introduced along the sigmoidoscope, will show that it is painful, that there is initial resistance to the tube of a spasmodic character, and that the tube is firmly grasped when it has been passed through and away up to the upper end of the sigmoid flexure or lower part of descending colon.

Stricture at this part is a common lesion in chronic rectal troubles, and without going into the matter further in the present paper, it is a condition which the writer has come to recognise and to deal with in the treatment of many forms of intestinal flux. The treatment consists of dilatation of the stricture, practised with the same intent as in cases of stricture of the urethra, and followed by as beneficial results in the rectal as in the urethral lesions. The nature of the stricture and the attendant clinical features of these two mucous tracts resemble each other closely, and their cure is effected by similar manipulations. To attempt to cure a sigmoido-rectal stricture by the introduction of a long tube without the sigmoidoscope, is to ensure failure. The sigmoidoscope must be introduced as far as possible, that is until mechanical

resistance and pain prevent its further introduction, and with the instrument held in position the œsophageal tube is passed along the tube of the instrument and held firmly against the sigmoido-rectal pylorus until the initial spasm is overcome, when it will slide up in the higher part of the bowel, with some pain, perhaps, but with the knowledge that the first step has been made in the cure of a rectal trouble which may have been of long duration and of a serious nature.

"Archiv. für Schiffs und Trop. Hyg.," vol. x., No. 2.

MALARIAL IMMUNITY.

Plehn, A., from clinical experience gained in Cameroon, concludes that personal immunity in a malarial district can only be relative and never complete. Old European residents in malarial countries seemingly attain an immunity, which is not a true immunity, but a mere tolerance which is not absolute. Any condition which tends to lower resistance, such as fatigue, sudden change in temperature, chills, accidents, or illness from any cause is apt to be attended by a suddenly increased virulence of the parasite or the toxins it produces. Malaria would seem to be latent in most, if not all, residents in malarial districts, and any departure from the even tenour of climate or the daily routine of life would seem to render the latent malaria active.

Natives of the Cameroon district who have never had febrile attacks, who have no enlargement of spleen, nor any signs of illness, may have malarial parasites in their blood; others, again, have enlarged spleens and some anæmia, and yet are free from fever. Neither of these states, however, betoken immunity, for were these persons subjected to depressing influence such as confinement in prison, attacks of fever are almost certain to result. The relative immunity of many natives seems to be inborn, that is to say, the child acquired immunity during fœtal life by being exposed to the endotoxins in the maternal blood; and after birth, although attacked by malarial parasites, which find their way into the blood through mosquito bites, yet is the child provided to some degree by the parasite poison present in its blood at birth.

Dr. Plehn is of opinion that Europeans arriving in a malarial district of the tropics can be also rendered relatively immune by the exhibition of quinine as a prophylactic. The quantity should be not less than seven grains, and the dose should be taken every fifth day, or if a large dose is preferred seven grains on consecutive days, either the fourth and fifth or the fifth and sixth. Quinine should be taken during the whole period of residence in a malarial district, and continued for at least six months after arrival in a non-malarial country.

When a large dose of quinine, say fifteen grains every fifth day, fails to prevent fever, the patient should be sent for change to a healthy (non-malarial) climate, and quinine administered every fifth day in seven grain doses for six months.

"Comptes Rendus de la Société de Biologie," November, 1905.

"Anopheles algeriensis et Myzomyia hispaniola convoient le paludisme." By Edmond and Etienne Sergent.

Messrs. Sergent have discovered the presence of sporozoit forms of the malarial parasite in the salivary glands of specimens of *Anopheles algeriensis* and *Myzomyia hispaniola*. These two mosquitoes have therefore to be added to the list of species capable of conveying malaria in Algeria; they are, however, both "wild," and are rarely found in dwelling-houses.—J. E. N.

Business Notices.

1.—The address of the JOURNAL OF TROPICAL MEDICINE is Messrs. BALE, SONS & DANIELSSON, Ltd., 83-91, Great Titchfield Street, London, W.

2.—All **literary communications** should be addressed **to the Editors.**

3.—All **business communications** and **payments,** either for subscriptions or advertisements, should be sent **to the Publishers** of the JOURNAL OF TROPICAL MEDICINE. Cheques to be crossed The Union Bank of London, Ltd.

4.—The Subscription, which is **Eighteen Shillings** per annum, may commence at any time, and is payable in advance.

5.—Change of address should be promptly notified.

6.—Non-receipt of copies of the Journal should be notified to the Publishers.

7.—The Journal will be issued on the first and fifteenth day of every month.

Reprints.

Contributors of Original Articles will be supplied FREE with six copies of the Journal if a request accompany the MS. If reprints are required they will be supplied by the publishers, if the order is given with remittance when sending the MS. The price will be as below:—

50	Copies of four pages,		5/-;
100	,,	,,	6/-;
200	,,	,,	7/6;
50	Copies beyond four up to eight pages,		8/6;
100	,,	,,	11/-;
200	,,	,,	14/6.

One page of the Journal equals 3 pp. of the reprint.

If a printed cover is desired the extra cost will be for 50 Copies, 5/6; 100 Copies, 6/6; 200 Copies, 7/6.

THE

Journal of Tropical Medicine

SEPTEMBER 15, 1906.

THE BRITISH MEDICAL ASSOCIATION MEETING AT TORONTO, CANADA, AUGUST 21 TO 24, 1906.

SOME 2,000 medical men attended the meeting of the British Medical Association, which was held in the buildings of the University of Toronto.

The meeting was a success in every way, the papers and discussion were scientifically valuable, the social arrangements were quite perfect, and the excursions to neighbouring and distant places of interest were carefully planned and conducted.

The retiring President, Mr. George Cooper Franklin, of Leicester, England, gave an account of the work of the Association during his year of office, and introduced the new President, Dr. R. A. Reeve, Dean of the University of Toronto. The Mayor of Toronto, Prof. J. H. Cameron, Prof. Alexander McPhedran and Dr. G. A. Bingham, delivered addresses of welcome on behalf of the city of Toronto, the local reception Committee, and of the Canadian and Ontario Medical Associations respectively.

The President, Dr. Reeve, after pointing out the cosmopolitan character of medical study, reviewed the early history and development of the British Medical Association, and referred to the advancement of medicine during the last ten years. Amongst the important subjects dealt with and advanced during

that period, he mentioned: (1) The new ideas brought forward in regard to the mechanical and chemical processes accompanying digestion, especially in the stomach; (2) the necessity for pure milk in the rearing of infants; (3) the researches in physiology by Sir Victor Horsley; (4) the discovery that pneumonia was a septic disease; (5) the introduction of "vaccine" for diphtheria and typhoid fever; (6) the discovery of a specific microbe in cerebrospinal meningitis; (7) the full recognition of the fact that yellow fever and malaria were carried by mosquitoes; (8) the extraordinary advances in preventive medicine.

The address in medicine was delivered by Sir James Barr, M.D., F.R.C.P. He chose for his subject "The Circulation Viewed from the Periphery."

Of the many interesting items in this erudite paper the following are noticeable: (1) As under normal circumstances a sufficient quantity of blood cannot get through the arterioles to keep the enormous capillary bed full, the lateral pressure and the velocity in the capillaries are ever-varying quantities; the pressure variations ranged from 50 to 2,000 mm. of water. (2) The variations of velocity of the blood in the capillaries amounted to from about 0·5 to 25 mm. per second. (3) The effects of gravity in the capillary pressure is an increase usually less than one-half of the hydrostatic effect, nor is the increase uniform, varying enormously in different individuals, and in the same individual under different conditions. (4) The viscosity of the blood is normally about five times that of distilled water, and in many diseases it amounts to nine or ten times that of distilled water. In Asiatic cholera the viscosity is often so great that it will not pass through the capillaries. A rise in temperature lessens the viscosity; the presence of carbonic acid gas in the blood is associated with diminished velocity and increases the viscosity, and Watson and Denning state that the chief resistance to the flow is due to the viscosity, and occurs in the capillaries. There seems, however, no doubt that the resistance to the arterial flow, and consequently to the heart, is situated in the first instance in the arteriole and small arteries and governed by vasomotor nerves. Were there not some such "first line of defence," the blood would gravitate into the more dependent parts, the cooling surface would be enormous, the capillary velocity would be diminished, the blood would become surcharged with carbonic acid gas, and we would become cold-blooded animals. By vasomotor mechanism a large amount of the cardiac energy is stored up in the arteries as potential, and is converted into kinetic energy in the arterioles and capillaries. Sir James Barr further discussed: The interchange of material through the capillary walls; the arterioles and capillaries of the skin; the arterioles and capillaries of the splanchnic area; the capillaries of the liver, the arterioles and capillaries of the kidneys and of the muscles; the cerebral vessels; the coronary vessels; the pulmonary circulation; the veins; the pressure in the veins; the velocity in the veins; the arteries, arterial blood pressure, and the heart.

Sir Victor Horsley, F.R.C.S., F.R.S., in his address in Surgery, dealt with "The Technique of Operations on the Nervous System." Surgical treatment of brain affections are undertaken for palliative or curative purposes. As a palliative measure against optic neuritis, which is so common a symptom of intracranial disease, it would seem that blindness may be averted with something like certainty by opening the subdural space early, and preferably in the basal temporal region of the right side, assuming that no attempt is made to attack the disease itself. Curative surgical procedures depend (1) On the nature of the intracranial disease; (2) the loss or aberration of nerve function it causes; (3) whether if the lesion be wholly extirpated there will be a recovery from the disorder of function; (4) whether any loss which may have been present before operation will be made permanent by the necessary extirpation of particular regions of the brain.

On points like the last it is evident that we cannot give a satisfactory opinion until we know precisely, first, what parts of the central nervous system alone contain the representation of movements or the record of sensation, and consequently of what parts does destruction entail permanent loss of function. In other words, we require to learn from the cerebral physiologist under what circumstances and to what extent can we get *compensation* of function when various parts of the cerebrum and cerebellum are destroyed.

(1) *As regards the Cerebrum.*—Apparently from the clinical records we can generalise thus far, that special motor functions cannot be restored if the whole of their cortical representation be removed. The same thing is probably also true of the special senses, and certainly is true of the hemianopic representation of sight. Succinctly stated, this amounts to the generalisation that compensation is not possible after the destructiun of middle leval centres. The higher sensory representation and *a fortiori* the intellectual functions are, on the contrary, not permanently abrogated by the destruction of any one part of the cerebral hemisphere. The net conclusion, however, must be that as little injury as possible should be done, and no more removed than is absolutely necessary.

(2) *As regards the Cerebellum.*—This question of compensatory power is of notable scientific interest when studied in the cerebrum, which is so clearly an assemblage of different nerve centres (in fact we might almost say organs), but it is no less interesting in the study of a homogenous structure like the cerebellum, and has assumed a particular importance in the present subject because of Professor Frazier's proposal to extirpate the lateral lobe of the cerebellum in preference to pushing it aside by displacement for the purpose of reaching deep-seated tumours. My own experience is against such extirpations for convenience. In fact, I regard them as an unnecessary mutilation, though quite admitting that in the process of removing a large tumour in that region the cerebellum is considerably bruised when so pushed aside. I ought to add that although I have removed a considerable number of lateral recess cerebellar growths, I have never found it necessary to do more than compress the cerebellum aside.

Sir Victor Horsley then proceeded to describe "Con-

sideration of the Details of Operative Procedure," and referred to (*a*) Previous Preparation ; (*b*) Anæsthesia; (*c*) Maintenance of the Body Temperature; (*d*) Hæmorrhage from arteries, arterioles and capillaries, and from veins. The address was illustrated by many excellent drawings.

The address in obstetrics was delivered by W. S. A. Griffith, M.D., F.R.C.P., F.R.C.S., who chose for his subject, "The Teaching of Obstetrics."

Section of Medicine.

President: Sir Thomas Barlow, Bart.

Dr. Percy M. Dawson (Baltimore) opened a discussion on "Blood Pressure in Relation to Disease." He stated that the pulse pressure might be taken as an index of the systolic output of the heart.

Dr. G. A. Gibson (Edinburgh) dealt with "Clinical Methods of Investigating Blood Pressure." The various factors concerned in keeping up the blood pressure are: the initial pressure or energy of the heart, the peripheral resistance, especially that of the splanchnic area, the elasticity of the vessel, the amount of blood in circulation and the viscosity of the blood. Estimating blood pressure by so-called *tactus eruditus* was condemned, and could only be gauged by modern instruments of precision. Observations should always be made with the patient in the horizontal position, owing to the variations due to various positions; and the variability noticeable according to the time of day the observations were made, and the influence of food and occupation were also insisted upon.

Sir William H. Broadbent, Bart., (London) discussed "The Clinical and Therapeutical Indications of Morbid Blood Pressure," and stated that *tactus eruditus* was the ultimate means of investigation, and that the real place of the instrumental investigation was the education of the finger.

Professor T. Clifford Allbutt (Cambridge) read a paper on "The Relation of Blood Pressure to Arterial Sclerosis." Arterial sclerosis may be apportioned under three headings: (1) The toxic, in some of which it is increased, as in lead poisoning; in some diminished, as in syphilis: (2) Hyperpietic (prolonged high pressure), in which there is considerable arterial stress, the majority being subjects of granular kidney ; (3) Involutionarily, met with in senile degradation, and associated with trophic or mechanical causes. These various groups of causes might be combined.

Dr. J. Mackenzie (Burnley), Dr. J. Lindsay Steven (Glasgow), Professor Alexander McPhedran (Toronto), and Dr. G. W. McCaskey joined in the discussion.

Dr. A. Stengel (Philadelphia) read a paper entitled "Some Clinical Manifestations, Visceral and general, of Arterio-sclerosis." He stated he had found continuous fever, lasting over considerable periods of time, in arterio-sclerosis without any local lesion to account for it, such as myelitis or other infection, and regarded the fever as possibly due to the active disorganisation of the tissues of the vessel wall, on the analogy of ferment fever.

Prof. Russell H. Chittenden (Yale) opened the discussion on "Over-nutrition and Under-nutrition, with Special Reference to Proteid Metabolism." Five men were fed for periods of from six to nine months on an average daily metabolism of from 5·4 to 8·99 grammes of nitrogen, *i.e.*, 34 to 56 grammes of proteid per day. In three cases, individuals of different weight, the amount of nitrogen required was 0·1 0·93 and 0·102 grammes respectively per kilogramme of body weight, amounted to not more than half of the Voit standard. Prof. Chittenden was of opinion that 0·1 gramme of proteid capable of metabolism per kilogramme represented the minimum proteid requirement, but it would probably be advisable to adopt a standard somewhat above this figure, and to give from 50 to 60 grammes of absorbable proteid to a man of from 60 to 70 kilogrammes weight, *i.e.*, a reduction of about 50 per cent.

Prof. Halliburton (London) was of opinion that if we reduced the amount of proteid to the minimum necessary to subserve the repair of waste of the tissues we should be dangerously near the margin, and little would be left as a source of energy. Dr. Otto Folin (Mass) said, at present there were no data whereby to determine the amount of proteid necessary.

Dr. Robert Hutchison (London) remarked that it would be interesting to ascertain the opsonic index in persons taking a lessened nitrogenous diet, in regard to various diseases producing organisms, and the way in which such individuals passed through an acute illness.

Prof. L. Lapicque (Paris), Dr. C. B. Ramarao (Madras), Sir James Grant (Ottawa), and Sir Thomas Barlow (London), took part in the discussion.

Dr. L. F. Barker (Baltimore) read a paper on "Amino-acids and Metabolism," the study of these acids present in foods showed that a human being took about the same quantity of these bodies, whether fish, white meats, or butcher's meat were taken, and the chemist was by synthesis now preparing from these a series of substances called peptides, viz., dipeptides, tripeptides, and polypeptides.

Dr. W. B. Thistle (Toronto) read a paper on "The Treatment of Typhoid Fever." Purgatives were suggested being given throughout the illness, so as to insure increased elimination of the typhoid organisms and their toxins. Calomel and salol were advocated as being at once purgative and antiseptic in the treatment of the disease. Dr. W. Caldwell (Belfast) said that the mortality of cases of typhoid fever which suffered from constipation during the course of the fever was less than those in cases in which diarrhœa was the rule, and therefore he avoided purgatives. Dr. F. M'Crae (Baltimore) said that typhoid was a blood or general infection, not a local intestinal affection, and therefore he withheld purgatives as unscientific, and intestinal antiseptics as useless. Dr. W. H. Neilson (Wisconsin), Prof. McPhedran, Dr. Barker, and Dr. J. H. Hamilton (Ontario) also joined in the discussion.

Dr. F. J. Smith (London), in a paper entitled "The Treatment of Typhoid," favoured a more varied diet than the milk and beef tea treatment ordinarily followed. The dread of perforation from food was exaggerated; perforation and hæmorrhage in typhoid had other causes than dietary. Any digestible food that was neither hard nor sharp-edged might be given in place of milk, which favoured fermentation at times, and was apt to cause distention and tympanites. The height of the temperature did not

negative departure from the milk *regime*. In cases in which the patient was disinclined for food, water and fruit juice might be given freely.

Dr. McCallum (Ontario) pointed out that it was difficult to state what a solid diet meant, for what was solid in the mouth might be fluid in the intestine, and *vice versa*.

Dr. R. Hutchinson (London) believed that to the lactic acid contained in it was probably due the beneficial action of milk; the question of diet, therefore, was not altogether a mechanical one.

Dr. McCaskey regarded milk as an unsafe diet in typhoid, considering the large masses of casein one found in the intestine in consequence of taking milk.

Sir Thomas Barlow remarked on the craving for food many typhoid patients developed, and it was a question whether it was always wise to deny them a suitably varied diet. Scraped beef or meat or fish passed through a seive, were often well tolerated in typhoid, and seemed to cause no special intestinal trouble.

Dr. D. G. Spiller (Philadelphia) described a case of syringomyelia, reaching from the sacral region of the cord upwards along the medulla oblongata, the right side of the pons, the right cerebral peduncle, and as far as the right internal capsule (syringobulbia).

In reply to Dr. C. Meyers, Dr. Spiller stated that he believed the sensation of pain (which was present in this case) was conducted by Gowers' tract, and not by the lateral columns.

Dr. S. Flexner (New York) read a paper on "The Serum Treatment of Cerebro-spinal Meningitis," in which he stated that he had succeeded in isolating an organism showing constant features, to which was assigned the name *Diplococcus intracellularis*. Against this he had prepared an antitoxin, made from monkeys, and 1 c.cm. of this substance injected into the spinal canal of a monkey which had previously received a lethal dose of the organism, prevented death. The signs and symptoms of the disease could be produced in monkeys by repeated doses of the toxin. Dr. L. Steven (Glasgow) said an outbreak of cerebro-spinal meningitis prevailed in Glasgow in March, 1906, and it was now included among the notifiable infectious diseases. Dr. MacFarlane (Albany) believed the best form of treatment in cerebro-spinal meningitis to be repeated tapping of the spinal canal. He was of opinion that the disease gained access to human beings by way of the pharynx. Seeing that it was impossible to inject fluid into the spinal canal in sufficient quantity to find its way to the cerebral cavity, the limitation of experimental meningitis to the spinal canal was probably explained. Dr. J. J. Putnam (Boston) compared "certain modern philosophic doctrines with regard to their relationship to the therapeutics of psychasthenia."

Dr. G. Doch (Ann Arbour) dealt with "Paracentesis of the Pericardium," stating that the operation was always attended by danger, be the precautions what they may. Posture seemed to have to do with the success of the operation, as, by altering the posture could fluid be drawn off. The angle between the xiphoid cartilage and the seventh left costal cartilage seemed the spot best suited for tapping the pericardium. Dr. T. B. McConnell (Montreal) mentioned a case of accumulation of fluid in the pericardium, successfully treated by tapping, and subsequent incision and drainage. Sir Thomas Barlow stated that he favoured incision in preference to aspiration in pericardial effusion, and said that fluid and fibrin collected behind the heart.

Dr. H. A. M'Callum (London, Ontario) introduced the subject of Gastric Neurasthenia, which was discussed by Drs. Putnam, McPhedran, Walsh and Caldwell.

Dr. Campbell Myers (Toronto) advocated spinal treatment for cases of acute mental disease during the preinsane stage. In this contention he was supported by Dr. Putnam (Boston).

Surgery.

President; Sir Hector Cameron.

Mr. Sinclair White (Sheffield) opened the discussion on "The Surgical Treatment of Ascites Secondary to Vascular Cirrhosis of the Liver." He proceeded to show the advantage of this operation, and stated that absolute proof has been obtained that epiplopexy leads, in suitable cases, to a remarkable development of anastomosing vessels between omentum and liver.

Mr. G. Guy Turner (Newcastle-on-Tyne) took part in the discussion.

Mr. John Lynn Thomas (Cardiff) read a paper on "Enucleation of the Prostate." He stated that enucleation of the prostate should be undertaken as soon as the patient was compelled to face the risks of "catheter life." He stated that there were no pronounced advantages of the suprapubic over the perineal method of enucleation so far as the incidence of mortality was concerned, but that the suprapubic operation showed slight advantage in regard to more complete removal of the organ. In the discussion which followed, a decided preference was shown, on the part of American surgeons, for the perineal route.

Dr. G. E. Armstrong (Montreal) reported a case of "Successful Removal of the Spleen in a Case of Banti's Disease."

Dr. Dow (Regina, Sark) showed a case of plastic surgery of the hip joint (arthroplasty), which had been successfully performed by introducing a layer of fascia and fat between the end of the divided femur.

Dr. Ingersoll Olmsted (Hamilton, Canada) in a paper on "The Surgical Treatment of Ulcerative Colitis," referred to the advantages of appendicostomy and irrigation of the intestine through a catheter, introduced into the appendix, after the manner originated and practised by Dr. Weir, of New York.

In a discussion on "The Surgical Treatment of Duodenal Ulcer," Dr. W. J. Mayo (Rochester, Minn.) recommended gastrojejunostomy as the most advantageous operation in chronic cases. In acute cases with perforation, transverse suture of the ulcerated and perforated area with pelvic drainage is indicated, with gastrojejunostomy subsequently. The results of this operation are eminently successful; of 175 reported cases of chronic duodenal ulcer operated on, two deaths only occurred; of ten cases operated upon for acute

perforation, four died; and of three cases operated upon for repeated hæmorrhage one died.

Mr. G. C. Franklin (Leicester) joined in the discussion, and mentioned that when a duodenal ulcer perforated the signs and symptoms were intense agonising pain in the upper part of abdomen, with locally rigid muscles.

Dr. B. E. McKenzie (Toronto) stated that in "The Treatment of Congenital Club-Foot," tenotomy and simple mechanical appliances were preferable to the more heroic measures in fashion. The tenotomy ought to be performed not earlier than the twelfth month of infant life.

Mr. Harold Stiles (Edinburgh) stated that he practised tarsectomy extensively in cases of club-foot, and claimed that by this means better and more speedy results were attainable than by tenotomy and mechanical appliances.

Prof. W. G. McCallum (Baltimore) in a paper entitled "The Surgical Relations of the Parathyroid Glands," stated that the acute tetany which occasionally followed removal of the thyroid gland, was owing to the fact that the parathyroid bodies were removed at the same time. The bodies referred to were met with, as a rule, along the course of the inferior thyroid arteries, but their number and position varied. That their removal was apt to cause tetany had been proved in both animals and man, and their preservation ought to be looked to during the steps of the operation for removal of the thyroid, when possible. Sir Victor Horsley discussed the paper.

Mr. C. J. Bond (Leicester) read a paper on "The Treatment of Acute Septic Peritonitis," in which he stated: (1) It is most important to avoid all unnecessary injury to the endothelium. (2) The diaphragmatic portion of the peritoneum is of great importance in the absorption of fluids and in phagocytosis. (3) Phagocytosis and the protection afforded by the endothelial cells lining the peritoneum constituted the first line of defence in injuries and diseases of the abdominal cavity. (4) Destruction of the cells opens the way for infection to be diffused by vascular or lymph channels. (5) Perforation of gastric or duodenal ulcers, followed by extravasation of the visceral contents into the peritoneal cavity was not followed by a virulent infection, and if early operation was practised curative results might be confidently anticipated. (6) Irrigation should be freely practised after laparotomy when gastric or duodenal contents, fæces, pus, bile or urine were found in the peritoneal cavity. (7) Irrigation should be withheld when the exudation into the peritoneal cavity was of a (*a*) sticky fibrinous nature; (*b*) when phagocytosis was likely to be disturbed; (*c*) and when the flushing of the cavity was likely to cause diffusion of the infective material. (8) In cases of gangrene of the intestine, and in local abscesses free drainage is a necessity. Dr. W. Howitt (Guelph), Dr. Murphy (Chicago), Dr. W. J. Mayo (Rochester) and others, joined in the discussion.

Mr. Jenkins (London) read a paper on "The Causation of Congenital Dislocation of the Hip." He ascribed the condition to be due to arrest in the bony development of the superior portion of the acetabulum.

Mr. G. G. Turner (Newcastle-on-Tyne) read a communication on "Intestinal Obstruction in Association with the Vermiform Appendix."

Dr. Parkins (Toronto) showed a case of multiple tumours in both breasts of a female patient.

Mr. C. H. Whiteford (Plymouth) showed a method of retaining a rubber catheter after external urethrotomy by means of what he termed a perineal stop.

A SIMPLE PREVENTIVE AGAINST MALARIA.

A CIRCULAR, published in English, Singalese and Tamil, is being circulated by the Ceylon Agricultural Society in Ceylon, drawing attention to the use of a composite oil for anointing the body to prevent mosquito bites. The suggestion is made by E. E. Green, F.E.S., and M. Kelway Bamber, F.C.S.

The constituents of the fluid suggested are citronella, kerosine, and cocoanut oils, with a certain proportion of carbolic acid. As an alternative for cocoanut oil, vaseline can be employed, but is more expensive.

Citronella oil alone is too dear for general use, and its effect is evanescent. Kerosine oil is similarly fugitive, and has the additional objection of an unpleasant smell.

It was found by experiment that a mixture of the above ingredients in certain proportions completely disguised the objectionable odours of kerosine and cocoanut oils, and produced a limpid liquid, smelling only of citronella, with a far more lasting effect. The mixture of the more inexpensive oils so reduces the cost that it can be freely employed on a large scale, and such a mixture could be easily produced locally on a commercial scale at a reasonable cost. The great difficulty with coolies is to induce them to take any precautions; but we know that they are always ready to anoint themselves either with cocoanut oil or with citronella if they can get it; but the latter is generally beyond their means.

All employers of labour in feverish localities should insist upon their coolies taking the simple precautions here suggested.

Every evening, at dusk, small quantities of the mixture should be rubbed over the legs and arms, and any other exposed parts, including the face; the oil is quite free from any harmful or unpleasant effect on skin.

Report.

THE HEALTH OF THE BRITISH NAVY—REPORT FOR THE YEAR 1904.

THE recently issued statistical report of the health of the Navy for the year 1904 extends to 197 pages.

The invaliding ratio of the total force amounted to 22·7 per 1,000, a decrease of 7·28 in comparison with the average for the last seven years.

The death-rate was 4·45 per 1,000, a decrease of 1·01 per 1,000 on the average of seven years.

The death-rate from disease alone was 3·14 per 1,000.

GENERAL DISEASES AND NUMBER OF CASES.

H. = Home; E.I. = East Indies; M. = Mediterranean; S.A. = South Atlantic; C. = China; N.A. = North America; I.F. = Irregular Force; A. = Australia; P. = Pacific; C.G.H. = Cape of Good Hope.

The following papers appear in the report:—

I.—SOME FURTHER POINTS IN THE ETIOLOGY OF MEDITERRANEAN FEVER, WITH PARTICULAR REFERENCE TO THE GROWTH OF THE SPECIFIC ORGANISM OUTSIDE THE BODY.

By Fleet-Surgeon P. W. BASSETT-SMITH, R.N.
Royal Naval Hospital, Haslar.

Major Horrocks, R.A.M.C., proved conclusively that the *Micrococcus melitensis* escapes by means of the urine from patients suffering from the disease. The urine thus containing the m.m. might then convey the disease by fresh or sea water, clothing or soil.

A few observations on similar lines were carried out and incorporated in the Report on the Etiology of Mediterranean Fever in the Health of the Navy, 1901, but the organism employed was derived from artificially infected human urine, or had grown for some period in urine, which did not appear in any way to reduce its vitality.

The most noticeable facts were that in even moderately alkaline urine the growth seemed to thrive for a time, not dying out until it gave a very considerable alkalinity (in one, that of standard decinormal soda solution), and that the larger the quantity of urine in the test tube infected, the longer the growth retained its vitality, and, of course, the grosser the original infection the more abundant the growth.

Fleet-Surgeon Bassett Smith by a series of experiments investigated the viability of the *M. melitensis* in sterilised urine, in sea water, in tap water, in fabric which had been infected and slowly dried, and in artificially infected dust.

The results of vitality of the m.m. outside the body shows that the m.m. can retain its vitality for a long period:—

(1) In urine which has become markedly alkaline.

(2) In fabrics which have become contaminated by urine containing the m.m.

(3) In sea and tap water infected by urine.

(4) In soil that has been infected by urine, and that has dried naturally.

From the experiments one may gather that in any endemic region where the sanitation is bad, it is easy for the dispersion of the organism and possible infection of the healthy to take place, quite apart from any agency of insects as secondary hosts.

II.—FURTHER NOTES ON THE DISTRIBUTION OF MEDITERRANEAN FEVER IN THE FLEET, WITH REFERENCE TO ITS ETIOLOGY.

By Fleet-Surgeon P. W. BASSETT-SMITH, R.N.
Haslar Hospital.

"In continuation of the statistical reports of the occurrence of Mediterranean fever, made in the years 1901, 1902, and 1903, I have again for 1904 made an abstract of the results from the special forms which have been filled in, details of which are given below. The total number of cases thus furnished is 260, as against 302 for 1903."

"Of these 260 cases 19 were relapses, giving a total of 241 fresh ones; some instances of the fever which occurred on the station have undoubtedly not been

included, none of these, probably, having been admitted into the Malta hospital."

"The diagnosis was confirmed in every case by the "serum reaction" test, either at Malta by Staff-Surgeon Gilmour, or by myself at Haslar."

"The observations of this year tend more conclusively than before to indicate that though sporadic cases of Mediterranean Fever do probably occur at other ports of the Mediterranean, by far the most prolific centre of infection is Malta itself."

III.—On the Agglutination Reaction in Mediterranean Fever.

By Staff-Surgeon E. A. Shaw, R.N.

Time of its Appearance.—Agglutination reaction is manifest in blood taken from cases quite early in the disease, viz., from two to five days.

Amount of Dilution in which it is Obtainable.—In a dilution of 1 in 2, the blood of healthy people and of patients suffering from other diseases will nearly always give it, and a large proportion of them will show traces of it in a dilution of 1 in 10.

Duration of Agglutinating Power after Appearance.—Birt and Lamb found it in all cases examined up to two years after the attack. After two years it was, in 8 out of 14 cases examined, no more marked than in people who had not had this fever; they record one case in which, seven and a-half years after recovery, there was still a complete reaction in a 1 in 20 dilution.

The phenomenon of agglutination in Mediterranean Fever is, as a rule, very marked and unmistakeable. The appearance of little white clumps, aggregations of micrococci, in the mixed drop of the specific serum and emulsion is frequently visible to the naked eye, especially on comparison with the control, and for the mere determination of the presence of agglutination in a 1 in 30 dilution, often a good pocket lens is sufficient after a certain amount of experience has been gained. It is advisable, however, especially at first, to commence with the low power of the microscope, the $\frac{2}{3}$-inch objective, arranging a feeble illumination; if a strong illumination be used, the micrococci, which, it must be remembered are not stained, will be practically invisible in the glare. Without disturbing the relative positions of the Abbé condenser and the plane mirror as used with the $\frac{1}{12}$-inch objective, the desired reduction of illumination can be obtained by racking down the two from near the stage till the upper surface of the Abbé condenser is very nearly an inch away from the upper surface of the stage on which the slide rests. Then, first wiping off all moisture from the under surface of the slide, and examining first the control—this, if properly made, will be found to present a very fine, faintly granular, appearance, without any indication of clumps then proceeding to the lowest dilution of specific (Malta fever) serum and micrococci, the latter, if agglutination has taken place, will be found aggregated into big clumps, or into a fine network spreading throughout the drop, usually both appearances will be present in the drop; then the higher dilutions should be examined, and the highest one in which agglutination has taken place, noted. No cover slips are necessary for the examination with the $\frac{2}{3}$-inch objective, but if, at the end of a couple of hours, no sign of agglutination can be detected with the $\frac{2}{3}$-inch objective, a small cover slip should be placed on the control and on the lowest dilution, and comparison made with the $\frac{1}{6}$-inch objective; this will necessitate the approaching of the Abbé condenser to within about $\frac{1}{4}$-inch of the surface of the stage, more light being required with the higher power, but, as before, a feeble illumination is best. If now no trace of agglutination can be detected, the result of the examination should be recorded as negative. It is highly desirable that, for the purpose of comparing the results obtained by different observers, some common standard should be agreed to. As regards density of emulsion used, this ideal is very difficult of attainment, but as regards length of time allowed for agglutination to appear and power of microscope used, there should be no difficulty. In the last hundred cases I have examined, I have invariably found agglutination, if present, to manifest itself in less than one hour, and to be visible under the $\frac{2}{3}$-inch objective. This reaction is much more marked and definite than the corresponding one in typhoid fever.

IV.—Notes on the Treatment and Symptoms of Mediterranean Fever.

By Fleet-Surgeon D. J. McNabb, R.N.

Forty-two cases are brought under notice and discussed in these notes.

In the general management of these cases it was found that they assimilated ordinary solid food with benefit to themselves, irrespective of high temperature.

Numerous drugs were tried without any appreciable result, the only one appearing to be of benefit being cyllin.

This drug is a preparation of the Jeyes' Sanitary Compounds Company, and appears to be a coal tar derivative.

The preparation used was pure cyllin in palatinoids, each palatinoid containing 3 minims of the drug.

The course of treatment by cyllin was inaugurated by a purgative such as calomel, and the drug was given at the rate of two palatinoids thrice daily.

It is non-poisonous, and its administration was followed by no unpleasant results.

Of the 42 cases under consideration 10 had neither pyrexia nor symptoms. These were dismissed from the list, and the remaining 32 dealt with.

These 32 cases are divided into 24 which were not treated with cyllin, and 8 cases in which the drug was tried.

The average duration of the cases not treated worked out at 70·6 days, while that of the cases where the drug was used was 38·5 days.

V.—The Year's Work at the Laboratory, Royal Naval Hospital, Malta, for 1904.

By Staff-Surgeon R. T. Gilmour, R.N.

The Agglutination Test in Mediterranean Fever and Enteric.—Eighteen hundred and ninety-eight specimens of blood were tested for these diseases. The reaction is of great aid to diagnosis, but not infallible.

The agglutination reaction may be present as early as the first day of the disease in Mediterranean fever; can usually be obtained in the first week; but may be delayed indefinitely. Cases with the symptoms of this fever are met with which never react.

The reaction rarely appears before the middle of the second week in enteric; in this disease also it it may be delayed, or never present.

The following deductions may be drawn :—

(1) At the commencement of convalescence there is usually a considerable drop in the reaction.

(2) In cases which relapse the agglutination test remains high.

(3) The reaction usually intermits before its final disappearance.

(4) Cases may have a negative reaction for several months, then react again.

(5) Cases may react up to eighteen months.

(6) Cases may only react for a few months.

(7) The agglutination reaction usually ceases during the second year of convalescence.

VI.—Compressed Air Illness and its Treatment by the Inhalation of Oxygen.

By Fleet-Surgeon Edward Pain Mourilyan, M.B., R.N.

The symptoms with which workers in compressed air, men employed in caissons and divers, are affected vary much in severity, and may be divided into two groups :—

(1) Those due to mechanical pressure, such as pains in ears, frontal and maxillary sinuses, and in carious teeth, headache, rupture of membrana tympani. These supervene on exit from compressed air and usually subside in a short time.

(2) Those, much graver, which are due to the actual presence of gas in the blood-vessels and to gas-embolism—*i.e.*, pains in limbs (the so-called "Bends") and joints, headache and vertigo, and other cerebral symptoms, deafness, dyspnœa, circulatory disturbances and paralysis. The paralyses do not supervene directly upon exit from pressure, but occur after a latent period of varying duration.

Oxygen is an important remedy in the prophylaxis and treatment of gas-embolism. By its use—its inhalation under stationary pressure—decompression can be rendered innocuous.

Symptoms of illness having set in, it promotes the separation of the gas in the right heart and assists the circulation. Combined with recompression, its therapeutical action is effected in the highest degree.

VII.—"Caisson" Disease (Diver's Palsy.)

By Fleet-Surgeon J. L. Barrington, R.N.

Royal Naval Hospital, Haulbowline.

Remarks.—The explanation of the condition in Caisson disease, like many other diseases of the nervous system, is still very obscure, and though the interest of the disease is centred in its pathology, the most that can be said for the various theories brought forward is that they are very indefinite and inconclusive. In one case reported by Leydens, death taking place on the fifteenth day, foci of hæmorrhages and signs of acute myelitis were found in the thoracic cord. In a case of Schultze, death occurring in two and a-half months, a disseminated myelitis was found in the thoracic region. In these cases slight fissures and lacerations were also found, as also in a third fatal case examined on the third day. One theory put forward is that the effects are due to liberated bubbles of nitrogen which have been absorbed into the blood during the high pressure. A second is that the symptoms are due to the pressure driving the blood from the surface into the great vertebral area of veins, followed by a revulsive anæmia, which, if true, would explain the temporary nature of the lesion in a case recorded by Fleet-Surgeon Barrington. In a second case, recorded by the same observer, the rise of temperature and temporary leucocytosis rather points, on the other hand, to a secondary inflammatory condition, the suddenness of the symptoms excluding inflammation as a primary cause. The paralysis was purely motor; there was no alteration in the sensation of touch, pain, heat or cold; the only sensory phenomena were shooting pains in the extremities. Now, since the sensory tract lies more towards the centre of the cord, and seeing that the reflex arcs were intact, one might hazard that minute sparsely scattered hæmorrhages in some of the motor tracts were the explanation of the symptoms.

VIII.—Notes of a Case of Splenic Anæmia.

By Staff-Surgeon Oswald Rees, M.D., R.N.

Shortly, *the symptoms of this rare disease are* :—Insidious onset and a fatal termination. In the blood, diminished hæmoglobia, a moderate erythrocyte anæmia (3,000,000 to 4,000,000), deformities of shape and polychromatophilia in severe and late cases, rare erythroblasts, marked leucopenic anæmia—(1,500-4,000), constituent leucocytes not much altered, but myelocytes in advanced stages—the spleen enormously enlarged, whilst the other lymphatics are not involved—pressure symptoms due to the enlarged spleen, dyspnœa, palpitation, dyspepsia, hæmatemesis, and epistaxis.

As regards the position of this disease in the official "Nomenclature of Disease," it would seem to fall most naturally between idiopathic anæmia and leuchæmia.

IX.—Ningpo Varnish Disease.

By Staff-Surgeon P. Hamilton Boyden, M.D., R.N.

This disease is an affection of the skin, chiefly of those parts exposed to the air, of an erythematous or eczematous character, caused by contact with or from sitting in a confined space recently painted with Ningpo varnish.

There are two kinds of varnishes :—

(1) Fat or oil varnishes.

(2) Spirit varnishes.

Their manufacture requires much skill and knowledge of the proper mixing of the ingredients, and in knowing how long they should be kept to mature before use.

In an oil varnish, to which variety Ningpo varnish

belongs, linseed oil is generally used as a vehicle; but in Ningpo varnish wood oil obtained from the Tung tree, growing plentifully in Mid-China, is made use of. The first process in the manufacture is to take a quantity of copal, which is a gum exuding spontaneously from the stems of various trees belonging to the genera, *Hymenda*, *Guibourtia*, and *Trachylobium*, found growing in the East and West Indies, and other parts of the world. The copal is melted in a pot, with a quantity of boiled linseed oil, by the aid of heat, until the mixture is perfectly clear; more oil is added in small quantities, and the mixture further boiled until it becomes stringy. The pot is then taken off the fire, and when cooled down sufficiently turpentine is gradually added, stirring all the while until the whole is thoroughly mixed; it is then strained and put aside until ready for use.

A quantity of Ningpo varnish was analysed and found to contain fat, an oleo-resin, a variety of copal, and a volatile acid, which were separated in the following manner:—The varnish was first of all treated with hot absolute alcohol, and so extracted the fat; the residue was treated with ether, which extracted the oleo-resin, leaving behind the very insoluble copal.

The volatile acid distilled over with the oleo-resin, and was separated by shaking up with water and evaporating the ether. The acid was in very small quantity, colourless, and had an irritating effect upon the unbroken skin.

The question now came to be as to the source of the oleo-resin and the irritative volatile acid, and one's thoughts naturally turned to the order, *Anacardianæ*, to which the genus *Rhus* belongs.

Rhus toxicodendron is a well-known irritant vesicant, and has a place in the United States Pharmacopœia.

In parts of China and Japan, *Rhus vernicifero* flourishes, and is used in Japan for making the celebrated lacquer.

I have found this tree growing plentifully in the higher parts of the Yang-tze valley, and think there is very little doubt that the oleo-resin from this tree is the basis of Ningpo varnish.

The varnish tree is a small, dicœcious tree, 10 to 15 feet high, with smooth branches and leaves, the latter being pinnate, and consisting of from 11 to 15 shiny green leaflets, from 2 to 3 inches long, and of an oblong form, with a long taper point. The fruit consists of racemes of small round berries, from the seeds of which Japan wax is expressed.

The manner of collecting the resin is as follows:—Incisions are made in the stem, and are repeated every fourth day at successively higher parts of the tree.

The inspissated juice is scraped off with a flat iron tool, and when the tree has been thus tapped to the topmost branches it is felled. The log is cut into lengths, which are tied into faggots and steeped in water for two or three weeks, after which the bark is pierced, and the oozing resin collected in the same way as from the stem. The juice thus obtained is a tenacious fluid of a greyish brown colour. It is allowed to stand and settle, when a kind of skin forms on the surface, the better quality rising to the top, and the impurities falling to the bottom. This fluid is highly corrosive, causing vesication and even ulceration of the skin, without actual contact, although it should be noted that, as in the case of other vegetable poisons—*e.g.*, *primula obconica*, also indigenous in China—many people are quite insusceptible to its action. As a rule, women and children are the greatest sufferers. In my own person, I have tried inhalation and also painting the varnish on the thin skin of the forearm, without any irritative effect being produced.

The volatile acid mentioned above has been investigated by several Japanese scientists. It is named "Urushic acid," derived from "Urushu," the Japanese word for the lacquer tree. This acid under the action of a ferment (a nitrogenous body), which is present in the fresh juice, rapidly becomes converted into oxy-urushic acid, of which I made mention before when noting the darkening in colour on exposure to the air.

A peculiar feature in reference to the application of the varnish is that it is always put on in damp weather, as it sets much better, and gets a harder and smoother surface.

The symptoms of varnish poisoning rival those imputed to the upas tree (*Antiaris*) of Java. The hands, arms, face, and in some cases the whole body, become greatly swollen from simply carrying a branch of the tree, or handling the varnish, the swelling being accompanied by intolerable pain and inflammation, and sometimes ending in ulceration. The treatment consists in the repeated application of a solution of *plumbi acetas*, which seems to have an almost specific effect in subduing the inflammation. The distribution of the disease is no doubt a very limited one, but I think it is of some importance for Medical Officers of His Majesty's Fleet to recognise that such an affection, which may at times assume a severe type, exists.

The varnish, being such an excellent one, is largely used by merchant ships trading in the Far East, and it is quite within the bounds of probability that commanding officers might make use of it, for varnishing the woodwork of His Majesty's ships, without knowledge of its dangerous properties; and if such cases did occur, a medical officer might be much exercised as to the cause of the outbreak if he were not acquainted with the symptoms of the disease.

X.—Cases resembling a Case of Dermatitis Repens.

By Fleet-Surgeon P. B. Handyside, R.N.

XI.—The Radical Cure of Inguinal Hernia.

By Fleet-Surgeon Vidal G. Thorpe, R.N.

Correspondence.

To the Editors of the Journal of Tropical Medicine.

Sir,—In reference to Dr. Hamilton Wright's article in your issue of August 15th, entitled, "Beri-beri: A Restatement and Reply to Some Criticisms," I beg to state that I do not consider I have misunderstood

his working hypothesis of the disease. My impression was that his "acute beri-beri" included the whole period marked "d" in his graphic illustration, namely, that during which the poison was formed, and a slight further period during which this poison continued to act, the whole corresponding to "g" in his diagram.

The lesions in the stomach and duodenum I found in thirteen out of thirty-four cases up to August, 1904, and in other cases in 1904 and 1905, but though common they cannot be said to have been "pretty constant." These lesions were found in persons dead in various stages of the disease, but in others they were absent both in early stages and in late stages. The nature of superficial lesions of the gastric mucosa is always difficult to determine, and when, as in beri-beri, there are also present nerve and vascular changes due to nerve poisoning, these difficulties are much increased. On macroscopic and microscopic examination I found nothing incompatible with the hypothesis that these changes were themselves secondary.

At no time have I "enunciated the pathological conception that this lesion cannot be primary." I did consider that it was necessary to test Wright's hypothesis by showing whether the condition was primary on other than histological grounds, and I therefore paid particular attention to the period assumed by Wright to exist, namely, that during which a gastro-duodenitis existed and no nerve lesions had developed—the period marked "c" in his diagram. Dr. Wright gives no instances of his own observation in support of his view. He gives histories which at most show that the patients complained of epigastric distress before they noticed any symptoms referable to nerve changes. Histories from natives and through native interpreters are not sufficient verification.

It was to this period "c," the only one in which the evidence could be conclusive, that most of my enquiries were directed, and I fully recognised that it was not the whole of the period during which Dr. Wright considered that the poison was being formed. In my own observations I did not find any cases in which the symptoms described by Wright were present without evidence of co-existent nerve lesions.

My use of the term "neuritis" is allowed by Dr. Wright as an alternative for "residual paralysis" in the Table of Contents and on page 1 of the "Studies of the Institute of Medical Research," vol. ii., Part II.

The subject is an important one, and it is well to clear up misunderstandings. Dr. Wright thinks I should have included clinical histories in my observations, but I venture to suggest that it would have been better if he had placed less reliance on such histories. With many of Dr. Wright's views I am in complete accord, and I recognise fully the admirable work he has done towards the clear enunciation of the problems presented by this disease, but I failed to find any satisfactory confirmation of the primary nature of the lesions he describes.

Yours, &c.,

C. W. DANIELS

New Instruments.

EVANS AND WORMULL, 31, Stamford Street, S.E., Surgical Instrument Makers, have sent us a copy of their comprehensive catalogue, which is well worth the perusal of any medical man who is about to make any purchases.

WE understand that Mr. Henry Gowlland, optician, of Selsey, Chichester, has perfected a new $\frac{1}{12}$ in. object glass, oil immersion, which he guarantees to be entirely of British manufacture, but what is of more importance to our readers, is that no soft glass is used in the objective, and that it will stand any climate. The objective is beautifully finished, and the price is only 55s., which compares very favourably with the objectives of foreign manufacture of the same power, which are retailed in this country at £5 and upwards. Intending purchasers would do well to write for further particulars before purchasing elsewhere.

Notes and News.

THE Report in the *United Provinces Gazette* of Major Chaytor White, I.M.S., as Chief Plague Officer of the United Provinces for 1905, is replete with practical interest. During the year 1905, plague existed in more or less epidemic form throughout the provinces. In many districts it was very severe, particularly in Muttra, where 45,644 deaths were registered, almost all occurring in the earlier months of the year under review. Only one district returned no seizures or deaths, viz., Almora. The total number of seizures reported in 1905 were 334,679, while the deaths totalled 305,737. It will be observed from the following figures that the deaths have progressively doubled in each of the last three years: (1903), 80,729; (1904), 166,620; (1905), 305,737. In the first five months of the year the mortality was most serious, but a marked change for the better has occurred during the plague season of 1905-6, so that there is hope that the disease is slowly dying out. The mortality for the first six months of the year was 300,039, while only 5,698 deaths occurred from July 1, to December 31. The disease has been uniformly more severe in rural areas.

Every inducement is offered to the people to evacuate infected sites, but they have not availed themselves of the facilities of the "health camps" established by Government to the extent that might be desired, and on this account reliance has still to be placed on disinfection. Disinfection by acid perchloride of mercury is still carried out. Izal, which was under trial in 1904, has not proved itself more efficacious than acid perchloride of mercury, moreover, the extra cost is against its use. Since December "cyllin" is being tried under the orders of the Government, and from the reports since received on its efficacy it is expected that it will prove a more effective disinfectant than the acid perchloride of mercury. The

same objection is present that is urged by natives against the use of phenyl—its smell—to which they strongly object. Phenyl is also used to a considerable extent.

Six thousand four hundred and eleven inoculations were performed throughout the provinces during the year 1905. Of these in Bareilly alone there were performed 5,194, against 3,010 in the previous year; this heads the list for inoculations in the provinces.

Phenyl, though a comparatively weak bactericide, it must be noted is a much better insecticide than the other agents mentioned, and it is probably owing to this that it has so often been found useful, to an extent that was inexplicable before the rat-flea hypothesis was accepted.

The details as to the results of rat-killing are most instructive, and it is satisfactory to find that it has been found possible to carry out this procedure without exciting undue opposition. This year rat killing was carried out on a large scale throughout the provinces. Only seven districts viz., Almora, Dehra Dun, Garhwal Saharanpur, Etah, Farrukhabad, and Mainpuri did no rat-killing. In Dehra Dun one rat only was killed. In all 851,167 rats were killed in 41 out of 48 districts.

Bareilly heads the lists in the year under report, and in it alone were killed 215,106 in five months. Allahabad comes next to Bareilly, and killed 77,345, Badaun and Agra killed 66,241 and 57,711 rats respectively, and ran third and fourth in the provinces. Badaun is only a small town of 39,031 inhabitants, but Mr. U. P. Allen, the collector, undertook the experiment of killing wholesale the rats in the town. This he did most effectively, letting out the work to contractors. The sum of Rs. 2,750 was spent on this work in Badaun, and not a single case of plague has occurred since the work was begun last monsoon up to now (March, 1906). Mr. Campbell, Collector of Bareilly, was also most energetic, and destroyed more rats than any other district officer. Out of the Rs. 100,000 at the disposal of the Inspector-General of Civil Hospitals, a sum of Rs. 24,850 was allotted for rat killing and general plague preventive measures. It may be mentioned that the above figures practically only refer to the last four or five months of the year, so that the efforts of the district officers were very real. From the plague returns, which have been received up to and during March, 1906 (usually the worst month in the year), it appears that the measures adopted have done much good in reducing the mortality, and the people undoubtedly believe that the measures adopted against rats have effected this. "Wonder" rat traps were used in almost all the municipalities and are much better than any other kind. They were distributed free to the public. Rewards are given to catchers for each rat caught, at different rates—generally two pice a rat and one pice a mouse. The rat poison called "Common Sense" is used by some municipalities and is well reported upon, no accident having occurred by its use. Opinions were obtained from the heads of the Medical Departments of various provinces as to the efficacy of the "Common Sense Poison" and all agreed that this poison is by far the best. Danyz' virus was tried in many places, but the results were not satisfactory. Special tubes were got out from England and distributed, but the opinion generally expressed was adverse. It is rather depressing, however, to find that Major Chaytor White considers that in villages rat-killing to a practical extent is almost impossible.

Lord Kitchener wants the Army to have its jam without the Gregory's powder. In a speech at the first meeting of the Standing Committee on enteric fever, his lordship suggested that the labours of the members should be directed to making antityphoid inoculation less unpleasant to the subject of the operation, even if the period of immunity were thereby curtailed.

The speech gives evidence of personal study of the question, but whether obtained through the action of spontaneous disease, or by the artificial process of inoculation, it is to be feared that immunity can only be gained at the cost of more or less personal discomfort.

The Indian Plague returns for the week ending July 28th show 562 deaths, a considerable drop as compared with the previous week's figures, after allowing for belated returns which swelled that week's total. Nearly half the mortality, viz., 262 deaths, occurred in Bombay. Madras reports only 6, and Bengal only 15; the United Provinces, 16; the Punjab, 11; Eastern Bengal, 4; Central Provinces, 1; Central India, 2; and Mysore, 37. Burma runs Bombay close with 208 deaths.

The total number of plague cases in Rangoon, however, for July, has been the heaviest since the outbreak of the epidemic in February, 1906. There were during the month 706 cases and 650 deaths.

The Indian Committee on Enteric.—On conclusion of the Commander-in-Chief's address, the Enteric Committee proceeded with their deliberations. They have since carefully considered the question of enteric fever with reference to its prevalence amongst various classes of individuals and communities in India. Statistics and evidence from the Army Medical Reports, the Annual Reports of the Sanitary Commissioner and others from the year 1856 were placed before them. The various sources of infection—excreta, fabrics, food, drink, &c., were discussed, and lines of present prophylaxis and a campaign for future prevention laid down. In the matter of cantonment sanitation the Committee had the advantage of the presence of the Inspecting Officer of cantonments (Lieutenant-Colonel Thornhill), whose views on this matter were of great assistance. The subject of antityphoid inoculation was fully dealt with. It is hoped the decisions arrived at and the line of action laid down will have marked beneficial results, not only on the health of the Army, but also to the community at large. The Committee, after four full days' sitting, have adjourned till the middle of October, when reports on the practical working of the various resolutions will be examined, and the recommendations, if necessary, added to.—*Pioneer Mail*, August 10th.

A good deal of disappointment is felt in Rangoon at the action of the Special Committee on Waterworks

in accepting the "Hlawga Scheme" in its present form. Instead of 40 gallons per head for a population of 650,000, at a total cost of about a quarter of a million sterling, the work actually accomplished can provide only 25 gallons per head for 207,000, and has cost over a third more than that sum; while, to provide for a population of 340,000 would cost twice as much as the original estimate, for nearly double the population. It is satisfactory, however, to find that all shades of public opinion appear to agree that a good and sufficient water supply is an absolute necessity to the town.

We reproduce from the August number of *The Indian Medical Gazette*, a letter to its Editor from Dr. E. S. Goodhue, which is of interest to all students of tropical medicine:—

THE BACILLUS LEPRÆ IN THE GNAT AND BED-BUG.

To the Editor of *The Indian Medical Gazette*.

DEAR SIR,—You will be glad to learn that Dr. W. J. Goodhue, Medical Superintendent of the Leper Settlement at Molokai, after several years of investigation there, has been able to demonstrate the *B. lepræ* of Hansen in the mosquito and in the bed-bug.

I will quote from Dr. Goodhue's official (but as yet private) report to the Hawaian Board of Health:—

"February 10th, 1906: We have since . . . . been sectioning mosquitoes taken from various leper houses, but until last June without any apparent success. At that time it appeared that we had isolated bacilli in these series of experiments, but, owing to the technique employed, it was impossible to confirm this . . . . This method of research was abandoned. . . . After repeated failures and the constant re-examination of fresh specimens, success has come as far as demonstrating the *B. lepræ* in the female mosquito (*Culex pungens*). . . .

"February 20th 1906: Since writing you I have discovered the bacillus of Hansen in the bed-bug (*Cimex lectularia*). . . . I believe that the *Cimex* is more of a factor in the spread of leprosy *among the natives* than the gnat" (here follow reasons).

Full reports of the work, with microphotographs of slides, &c., will be given publicity in May. You will kindly keep the matter confidential until May 8th, when you will be free to use it. We should be glad to have your Journal containing notices of the discovery.

Yours very truly,

Hawaii. E. S. GOODHUE,
April 9th, 1906. *Government Physician.*

That the agency of parasites should explain the mystery of the method of transmission of leprosy becomes increasingly probable, as parallel cases continue to be proven in etiology of other diseases. Our knowledge of the facility of accidental and intentional inoculation in the case of many diseases, makes it almost inconceivable that biting parasites should not, at least occasionally, act as inoculators; but in the case of leprosy, the failure of all attempts to produce direct infection makes it probable that some special parasite must be concerned, within which the virulence of the bacillus, as found in the human tissues, is enhanced.

In an Editorial our contemporary ably discusses Mr. Jonathan Hutchinson's recent book on "Leprosy and Fish-Eating." That the fish causation theory should be rejected by anyone with an extended acquaintance of Indian facts relating to leprosy is a foregone conclusion, as it is impossible to practice long in the country without meeting with lepers who, it is morally certain, would die at the stake rather than touch fish in any form, whether salted or fresh, newly caught, or in any stage of decomposition. In India, as elsewhere, leprosy is specially a disease of the verminous poor, but it is certainly no respecter of caste; though the peculiar dietetic limitations that are imposed by the caste system, and the rigidity with which they are carried out, should make India the best of all fields for the investigation of any food causation theory. Many castes will not touch fish, while others consume it largely; and the fact that leprosy is not practically confined to, or even specially common in the latter, is a sufficient demonstration that the theory in question is no better than an improbable fad.

On the other hand, the writer evidently considers that the last has not been heard of Capt. Rost's scarcity of salt theory, as he concludes his remarks with the following paragraph:—

We have no intention of bringing forward, without proof, a salt hypothesis, as opposed to a fish hypothesis, and as being the last word on the leprosy question. It is, of course, as readers of *The Indian Medical Gazette* are aware, not a new one, and we hope shortly to be able to test it in certain directions which we believe have never been attempted—a matter which is of some interest, as we understand that it is quite impossible to consider the Kasauli tests as final.

Personal Notes.

INDIAN MEDICAL SERVICES.

Arrivals Reported in London.—Major B. C. Oldham, Major H. St. J. Fraser.

Extensions of Leave.—Captain H. Hugo, D.S.O., furlough to December 12th, 1906; Major J. Chaytor White, 6 w., medical certificate; Major J. K. Close, study leave, May 1st to July 31st, 1906; Captain E. L. Perry, study leave, February 1st to March 31st, and May 1st to June 26th, 1906; Lieutenant-Colonel W. B. Browning, C.I.E., 1 m. 14 d., medical certificate; Major A. R. O. Russell, 6 m., medical certificate; Captain A. E. J. Lister, 1 m., medical certificate; Lieutenant J. W. H. Babington, 14 d.

Permitted to Return to Duty.—Major H. E. Drake-Brockman, Lieutenant J. W. H. Babington, Major L. F. Childe, Captain J. B. Christian, Captain R. L. Hagger, Captain R. D. Willcocks, Lieutenant-Colonel W. Coates, Major S. H. Henderson, Lieutenant-Colonel H. Fooks, Captain A. B. Fry.

Retirements.

Lieutenant-Colonel D. Prain and Lieutenant-Colonel Mawson are permitted to retire.

Promotion.

Captain Ross Pearce, M.B., to be Major.

Postings.

Captains F. A. Barnado and L. Cook, services lent to Government of Bengal.

Captains H. B. Steen, O. Moses and H. A. J. Gidney, services lent to the Government, East Bengal and Assam.

Captain W. S. Patton, services temporarily lent to Government, Madras; and of Captain Stewart and Lieutenant Proctor, for service on a Drainage Committee.

Captain M. Dick acts as Health Officer, Rangoon.

Lieutenant-Colonel J. Carmichael, R.A.M.C., to the Command of the Station Hospital, Jullundur.

Captain D. S. A. O'Keefe, to Medical Charge, 26th Punjabis.

Captain R. G. Easton, to Medical Charge, 22nd Punjabis.
Captain N. W. Jeendine, to Medical Charge, 27th Punjabis.
Captain T. C. McC. Young, to Medical Charge, 34th Sikh Pioneers.
Captain E. A. Walker, to Medical Charge, 36th Sikhs.
Captain J. Woods, to Medical Charge, 53rd Sikhs.
The undermentioned officers of the Indian Medical Service are appointed specialists in the subjects noted:—Fevers: Major Wimberley, 3rd (Lahore) Division. Prevention of Disease: Lieutenants Proctor, Umballa, and Ingram Aden. Captain Keys is appointed specialist in Midwifery and Diseases of Women and Children in the Western Command.
The undermentioned officers of the Royal Army Medical Corps are permitted to continue in their appointments of specialists in the subjects noted:—Fevers: Major Clark, 1st (Peshawar) Division; Captain Huddleston, 5th (Mhow) Division; and Captain Hopkins, 6th (Poona) Division. Skiagraphy: Major Boyle, Burma Division; and Captain Grech, 7th (Meerut) Division. Dentistry: Lieutenant Bowle, 5th (Mhow) Division. Ophthalmology: Major McDermott, Eastern Command; and Captain Kiddle, Western Command.
The undermentioned officers of the Royal Army Medical Corps, on return from leave, are appointed specialists in the subjects noted:—Operative Surgery: Major Cameron, 3rd (Lahore) Division. Midwifery and Diseases of Women and Children: Captain Maurice, Eastern Command. Laryngology: Captain Profeit, Northern Command. Otology: Captain Berne, Western Command.
Military Assistant-Surgeon C. A. Owen, M.D., I.S.M.D., officiates as Civil Surgeon, Shahpur.
Captain J. Stephenson, to be Civil Surgeon, Umballa.
Captain C. A. Lane, to be Civil Surgeon, Purnea.
Major Brend, to be Inspector-General, Prisons, Punjab, in succession to Major Macnamara, who is transferred to Madras, in the same capacity.
Captain W. C. H. Forster is placed on special duty under the Sanitary Commissioner with Government of India.
Major O'Kinealy acts as Professor of Ophthalmic Surgery, Calcutta.
Captain S. L. Marjoribanks, to be Deputy Sanitary Commissioner, Western Registration District.
Captain F. H. G. Hutchinson, to be Deputy Sanitary Commissioner, Southern Registration District.
Captain R. W. Antony, to be Civil Surgeon, Ratnagiri.
Major L. Rogers, Major D. M. Moir and Dr. Annandale are appointed Fellows of the Calcutta University.
Captain E. Bisset assumes charge of civil medical duties of the Kohat District.
Lieutenant W. Tarr assumes Civil Medical Charge of Sheih Budin.
Captain W. H. Cazaly, to be Civil Surgeon, Satara.
Captain A. G. Sargent, to be Civil Surgeon, Panch Mahals.

Leave.

Major B. Oldham, combined leave, 15 m.
Major Maynard, Professor of Ophthalmology, Calcutta, privilege leave, 3 m.
Captain W. C. Ross, Deputy Sanitary Commissioner, Oussa Carch, privilege leave, 2 m, 23 d.
Captain C. J. Robertson Milne, services replaced at disposal, Government of Bengal.
Captain W. S. J. Shaw, services temporarily lent to Government of Punjab.
Captain C. A. Gourlay, services placed permanently at disposal, Government, East Bengal and Assam, in Sanitary Department.
Captain F. Wall, 62nd Punjabis, to additional civil charge of Fyzabad District.

Colonial Civil Service.

Dr. A. Morrison has retired from the office of Government Botanist of Western Australia.
The Hon. Dr. F. Watts, C.M.G., Government Chemist and Superintendent of Agriculture, Leeward Island, has left the Colony on leave for four months, during which Mr. H. Tempany will perform his duties.

PLAGUE.

Prevalence of the Disease.

Clean Bills of Health issued for Hong Kong on August 29th.
Australia.—During the week ended July 21st, 1 case of plague at Cairus, Queensland. No other cases of plague reported from July 7th to August 4th in any part of Australia.
South Africa.—No cases of plague from July 7th to August 18th.

THE SLEEPING SICKNESS.

King Leopold and the Liverpool School of Tropical Medicine.

In view of the alarming nature of the recent reports with regard to the spread of sleeping sickness in Africa, and of the fact that an expedition organised by the Liverpool School of Tropical Medicine has been studying this disease for three years in the Congo, Sir Alfred Jones, president of the school, requested an audience of the King of the Belgians in order to confer with him upon the subject. In a recent letter to the secretaries of the reform committee King Leopold referred to his deep interest in this matter, and, besides offering a prize of 200,000f. (£8,000) for the person who should discover a remedy, he has placed a credit of 300,000f. (£12,000) in the Congo estimates for the purpose of prophylactic research.
The committee of the School were received at the Palace, on August 23rd, at noon. The representatives present included the president, Sir Alfred Jones, Professor Ronald Ross, C.B., F.R.S., Professor Boyce, F.R.S., Dr. J. W. W. Stephens, Dr. J. L. Todd, Mr. R. Newstead, Dr. Evans, and Mr. A. H. Milne. The King gave a most attentive hearing to the views of the experts of the school on the necessity of preventing the further spread of sleeping sickness. He agreed with Sir A. Jones that the question was one of international importance, and said that, as far as he was concerned, he was prepared to do all in his power to relieve both the white and black population from the terrible dread of this scourge. His Majesty asked the Liverpool School to submit to him a scheme for the prevention of the disease, and this request will be acted upon as soon as possible. He has promised his co-operation if it is in any way feasible or practical. The King expressed in high terms his appreciation of the energetic work now being carried on by the school and of the thorough manner in which its expeditions are worked. In conclusion, to show the value he placed upon that work, he bestowed the Order of

Leopold upon Professor Ross, Professor Boyce, and Dr. J. L. Todd, the last-named of whom worked on trypanosomiasis in the Congo Free State for three years.

The conference was followed by a luncheon at the Palace to the representatives of the Liverpool School. Among those present were Baron Wahis, Governor-General of the Congo, Commandant Liebrechts, Secretary-General of the Home Department, and other leading representatives of the Brussels Administration.—*Times*, August 24th, 1906.

UNIVERSITY OF CAMBRIDGE.

Diploma of Tropical Medicine and Hygiene. D.T.M. and H. (Camb.)

The following candidates qualified for the Diploma during the year, 1906:—February, 1906—J. Booth-Clarkson, J. C. S. McDowell, R. Small; August, 1906—Samuel Anderson, Robert Thomas Booth, Charles Walter Holden, Thomas Campion Lauder, Harry Strickland McGill, Edward McKillop Nicholl, Ambrose Thomas Stanton, Lessel Philip Stephen, Edmund Wilkinson, Andrew Watson Cook Young.

Examiners { George H. F. Nuttall. Ronald Ross. C. W. Daniels.

Recent and Current Literature.

A tabulated list of recent publications and articles bearing on tropical diseases is given below. To readers interested in any branch of tropical literature mentioned in these lists the Editors of the Journal of Tropical Medicine *will be pleased, when possible, to send, on application, the medical journals in which the articles appear.*

"Proceedings of the Royal Society," vol. lxxviii., No. B. 522.

"The Microscopic Changes in the Nervous System in a case of Chronic Dourine. Comparison with those found in Sleeping Sickness."

Mott, F. W., M.D., F.R.S., states the result of an investigation in the nervous tissues of an Arab stallion which acquired Dourine or *mal de coit*, by infective coitus. The tissues were forwarded by Dr. Lingard of the Imperial Bacteriologist Laboratory of India. The result of the investigation demonstrated that in Dourine, in animals inoculated with *Trypanosoma gambiense* and in human sleeping sickness, chronic trypanosome infection sets up a lymphadenitis and a chronic inflammation of the lymphatics of the central nervous system. As the result of these inflammatory states, a chronic interstitial condition of the lymphatics of the soft membranes, the subpial septa and the perivascular spaces, without any pronounced destruction of the neural elements. Of this chronic interstitial change the cell proliferation of the neuroglia is the primary evidence; and it is surmised, from the knowledge attained by observing chronic trypanosomiasis in animals, that the lymphocyte accumulation and proliferation is of a secondary character and in part the result of the changes referred to in the neuroglia.

In view of the fact that Dourine is caused by a specific form of trypanosome conveyed during coitus in the horse, Schaudinn's demonstration of the spirochætæ pallida in syphilis is daily acquiring increased significance and interest. Dourine may be shortly described in the light of recent knowledge as "Horse Syphilis."

"Indian Medical Gazette," June, 1906.

(1) Splenic Abscess in Malarial Fever.

Anderson, A. R. S., Major I. M. S., describes two cases of splenic abscess in Hindu male prisoners in Port Blair Gaol, Andaman Islands. In both cases there had been a long previous history of malarial fever and enlarged spleen. In one case no malarial parasites were found, probably owing to quinine administration; in the other case malignant tertian parasites were found. A slough was found in one case; in the other no ponderable slough, but a quantity of broken-down splenic tissue. Of 77,949 patients suffering from malarial fever, seen by Major Anderson during the past five years, these are the only two cases in which splenic abscesses were diagnosed. In three other spleens, out of a total of 178 fatal cases reported upon, splenic abscesses, or the condition possibly precedent to such abscesses, were found. In one spleen were several hæmorrhagic infarcts; in a second numerous miliary abscesses; and in the third several small abscesses.

Of the two cases operated upon by Major Anderson, one recovered and was well five years afterwards, the other survived the operation nine months, subsequently dying from pyæmia.

(2) "Cysticercus Cellulosæ of Tongue, with a Note on the Helminthology of one of the Madras Jails."

Williams, C. L., Major, I.M.S., found a cystic swelling about the size of a hazel nut in the under-surface of the left side of the tip of the tongue of a convict in the jail at Coimbatore, Madras Presidency, India. From the swelling when cut down upon, the head of a Tœnia Solium was enucleated. The district of Coimbatore seems to be in distinct contrast to the reported prevalent infection of the alimentary canal of the natives of India generally, for, as a rule, the natives of Coimbatore are wonderfully free from "worms."

"Ann. de l'Inst. Pasteur," May, 1906.

Antidysenteric Serum.

Vaillard and Dopter found that the serum from horses which have been immunised against the dysentery bacillus is applicable and useful in dysentery in man. The prepared horse serum has anti-bacterial and anti-toxic properties, and when injected in doses proportionate to the severity of the dysenteric attack remedial effects speedily result. The injection should be given early in the disease, but even as late as the sixteenth day in acute dysentery the treatment is efficient.

"Riv. Crit. di Clin. Med.," 1906.

Splenocleisis.

Schiassi, B., in a case of enlarged spleen and marked anæmia, cut down on the spleen, scraped the surface with a sharp spoon, enveloped the spleen in five layers of gauze and sewed the wound up, leaving, however, the ends of the strips of gauze protruding from the upper and lower ends of the wound. The strips were removed one by one from the fifth to the ninth day after operation. The patient did well, the blood count rose in six months (that is from before until after operation) from 3¼ to 5½ million red cells, hæmoglobin from 24 per cent. to 92, and white cells from 1,600 to 6,200. In true splenic anæmia the only signs and symptoms are enlargement of the spleen and anæmia, both of which tend to increase. The success of this operation is encouraging.

Notices to Correspondents.

1.—Manuscripts sent in cannot be returned.

2.—As our contributors are for the most part resident abroad, proofs will not be submitted to those dwelling outside the United Kingdom, unless specially desired and arranged for.

3.—To ensure accuracy in printing it is specially requested that all communications should be written clearly.

4.—Authors desiring reprints of their communications to the Journal of Tropical Medicine should communicate with the Publishers.

Original Communications.

NILE BOILS.

By Frank Cole Madden, M.D.Melb., F.R.C.S.Eng.

Professor of Surgery, Egyptian Government School of Medicine; Senior Surgeon, Kasr-el-Ainy Hospital, Cairo.

During the hot months, and particularly in the damp weather towards the end of the summer, and also at the changes of season, residents of Egypt frequently suffer from a peculiarly painful boil (or boils), which has so many distinctive features as to justify a more detailed description than has hitherto, so far as I am aware, been devoted to it.

The European residents are probably more often attacked than the native Egyptians, though the latter are not by any means exempt. In their case, however, the condition about to be described is included with many other pustular lesions, due to the heat and excessive sweating, in the all-embracing title of "Hamm en-Nil," which, to the native mind, is sufficiently comprehensive to connote any skin eruption from a prickly heat to a general furunculosis. Though thus almost lost sight of among its many distant relatives, true Nile boil does occasionally occur.

A form of boil, the so-called "Bouton de Nil," next of kin to the Delhi boil, the Aleppo boil, and the Biskra button, as described by Manson, Briault, and other observers, is essentially a chronic process, and in my eight years' experience in Egypt I have never met with such a condition, either in hospital or private practice. The boil we are accustomed to call the Nile boil is an acute inflammatory and exceedingly painful condition, which does not last more than fourteen days from beginning to end.

As has already been mentioned, the boil is particularly frequent at the end of the summer, when the Nile is rising or is in flood, and the weather is very damp, and also in the early spring, that is to say, at the end of the cold season. In certain cases it occurs when the patient is much "run down," or after one of the infectious fevers, but is just as frequently met with when he is in the rudest health. Food, drink, or water do not seem to influence its occurrence, and no *régime* or diet appears to prevent it. One is liable to have attacks of boils at long intervals, sometimes every summer, or to have a series of boils one after the other, which persist for a long time. The boils also have an unfortunate habit of developing in particularly tender places, some of their favourite seats being the perinæum, especially all round the anus, the buttocks, the arms, the hands and the fingers, and the face. They are not so common on the neck or on the lower extremities below the buttocks, though they are to be found on any part of the skin surface, and even within the external auditory meatus. They are more common in men than in women, but are no respecters of age or sex, though, fortunately, they do not often occur in young children.

Having been myself the subject of Nile boils on no less than four occasions, I can speak with some authority on the matter, and cannot do better than describe my feelings in detail, reinforcing my own personal reminiscences with certain additional facts I have observed in other fellow-sufferers.

On accidentally rubbing my forearm with my cuff, I felt a distinctly painful point which, on close examination, I found to be a minute red spot at the base of a hair, in the hair follicle. In a few hours' time the redness was more evident and the spot was slightly raised around the base of the hair; the tenderness, even at this stage, was altogether out of all proportion to the naked eye appearances, the least friction of the shirt sleeves being quite painful. During the night I was conscious of a transient throbbing in the spot and found myself taking unusual care to place the arm in a comfortable position.

In the morning there was a red swelling the size of a sixpence, not unlike an ordinary blind boil, which was very painful, throbbed horribly, and was acutely tender to the least touch. The skin around the hair was dusky and was surrounded by a zone of dark red inflammation, fading off to a hyperæmic redness beyond. The central portion of the swollen lump was very hard and indurated, the indurated piece feeling as though it were let into the deeper parts of the skin. By mid-day the lump had increased in size and was even more tender than before. The surrounding inflammation had also increased in proportion. Thin, tender, red lines of inflamed lymphatics could now be seen, and there was pain above the elbow and in the axilla. A tiny blister had formed in the centre of the boil and this burst on extracting the hair and exposed beneath it the top of a pea-green-coloured slough, which was firmly attached all round to the surrounding inflamed tissues. The colour and the characters of this slough is very typical and its appearance confirms the diagnosis.

From this time onwards the swelling generally increased until it reached the size of the palm of the hand, and it exhibited all degrees of acute inflammation with the green chamois leather-like slough in the centre. The hard induration was now the size of a florin and the whole of the inflamed area was œdematous and pitted on pressure. The point of acutest pain was immediately around the slough.

On the fourth day a drop of thick pus was squeezed out from beside the now much enlarged slough, but without any relief whatever. The slough was still firm all round, except just at the skin surface, and gave me the idea of being screwed into the bone in the depths of the boil. The lymphangitis and the pain in the axilla increased and the lymphatic glands were enlarged and tender. The arm was absolutely useless, felt as heavy as lead, throbbed violently on any sudden movement, and could not find a comfortable place for itself anywhere.

On the fifth day, by dint of hot fomentations, the slough, which was now more yellow in colour, looked looser, and a vigorous squeeze caused the greater part of it to pop out. It looked like a partially macerated bean, and was coated with thick pus. The remains of the slough still holding on tight to the depths of the boil, had to be picked out with dissecting forceps, and a small quantity of thick, slimy-looking pus was finally squeezed out. There was then left a crater-like cavity with sharply cut though rather eaten-out edges, in the midst of a still much inflamed and indurated area of

skin; but from the moment of the loosening and subsequent removal of the slough, the pain vanished as if by magic, and the part, though still hard and inflamed, was quite painless and could be handled and squeezed with impunity. Indeed, save for the redness and the crater it was difficult to believe that a short time before one was in such severe pain.

The next morning the cavity had filled in a great deal and a little sero-pus could be squeezed out; by evening it had nearly all filled with granulation tissue and was coated with a thin layer of coagulated serum.

In two days' time the sore had quite healed, the redness had markedly diminished, and a small hard lump was all that remained of the induration. A permanent scar, covered thinly with skin, remains, or a small mass of keloid forms in the scar. Throughout the whole period, up to the time of the expulsion of the slough, a very small quantity of serous discharge was found on the dressings. I have had two boils in adjoining follicles, which, starting on different days, made the whole course of the disease longer; but, though there is a larger scar from the fusion of the two craters, the symptoms were substantially as just described. Infection of neighbouring follicles naturally frequently results. When crops of boils occur, as is sometimes the case in the perinæum, on the loins or on the face, during the time of their acuteness, the local as well as the general symptoms may be so severe as to give rise to some anxiety. I felt perfectly well in myself when the boils broke out, but by the third day I felt distinctly "seedy," with all the usual accompaniments of fever, including a general malaise, loss of appetite, headache, sleeplessness, &c. In some cases when a large number of boils develop one after the other, the constitutional symptoms may be severe.

Professor Symmers made a culture directly from the slough, on the third day of the disease, and grew a pure culture of *Staphylococcus pyogenes aureus*. In severe cases a spreading cellulitis may supervene, or, more usually, an abscess form just beyond the limits of the boil, and, rarely, all the more serious septic consequences may ensue.

Treatment is most unsatisfactory. In the very early stage an attempt, which it must be admitted is very rarely successful, may be made to abort the boil by extracting the hair and injecting a drop or two of pure carbolic into the reddened follicle.

Once the boil has got beyond the initial stage the hair should be extracted and hot sublimate or lysol fomentations, or antiseptic linseed poultices, applied and changed as often as possible. These hot applications in my experience are the only measures that afford any relief. Each time they are changed the part should be soaked in water, as hot as can be borne, for ten minutes before the fomentation is re-applied.

It is not the least use trying to squeeze out the slough until it is loose. It will not come out and the squeezing only increases the pain and the throbbing. Sometimes it comes out of itself on the fomentations on the fifth day. Even after its removal the fomentations are best continued for another twelve hours, after which the part may be dressed with vaseline or boracic ointment. Splints and other appliances to immobilise the inflamed parts must be used as necessary, and all complications treated as they arise.

Little is usually required in the way of general treatment, except an efficient aperient in the earlier stages, a low diet, and rest. I have tried calcium sulphide, sulphur, sulphate of magnesia, and many other drugs without any good result, nor have I seen any effect from yeast in any form.

Once a boil has developed it is a good plan to pull out the surrounding hairs to prevent infection, but I know of no remedy of any service as a prophylactic.

I would, with all respect, venture to affirm that the condition, hitherto described as the Nile boil, or "Bouton de Nil," does not now exist in Egypt; but there is a particular form of boil peculiar to the country, characterised by the intensity of its inflammation, its extraordinary and early tenderness and pain, out of all proportion to its naked eye appearances, its characteristic slough and very scanty serous discharge, its rounded button of hard induration, and its resistance to treatment, until it has run its own course, which is a distinct pathological entity and a worthy successor to the title so long borne by its better-known predecessor.

THREE CASES OF INFECTION WITH *SCHISTOSOMA JAPONICUM* IN CHINESE SUBJECTS.

By O. T. Logan, M.D.

Medical Missionary, Changteh, Hunan, China.

I am led to contribute this paper for three reasons: (1) To help define the geographical distribution of the fluke. (2) To give an idea of the form of the egg and embryo as it is seen in the stool. It seems very unfortunate that none of the current numbers of this Journal nor the latest, and one might safely say the only, book in English on the subject of animal parasites in man, should have failed to give drawings of the ova or embryo that would enable one to recognise the presence of this fluke. (3) To show the effect of treatment.

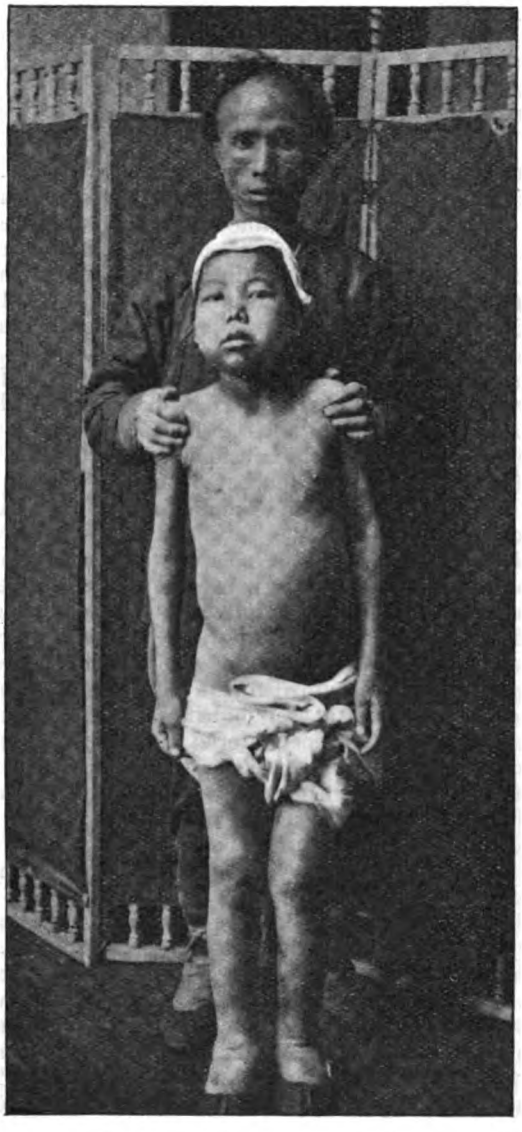
Our first case has been reported in full, at my request, by Dr. Beyer,[1] who, with Drs. Stiles and Lovering, identified and measured the eggs in the specimen of fæcal matter sent by the writer. They found the average measurement of nine eggs to be 72 microns in length and 48 microns in width. Thus it will be seen that the egg is only a little larger than that of the *Ascaris lumbricoides*—a very important matter for the novice in fæcal examination to note.

Our second case is especially instructive in that it shows the good effects of treatment, and offers hope that some of these patients may outlive the parasite and eventually be cured. The notes on this case are as follows:—

Tsen, male, aged 13. Born and reared in Hunan Province; Changteh Prefecture. Occupation, farmer. It should be stated that one of the duties of farmers,

[1] "A Second Case of Infection with the Asiatic Blood Fluke (*Schistosoma Japonicum*)," by H. G. Beyer, Medical Inspector, United States Navy. *American Medicine*, vol. x., No. 14, pp. 578-579, September 30th, 1905.

in this district at least, is to fish in the ponds that are always near the houses of the farmers. This means that there must be a good deal of wading, as the small seine is one of the commonest implements used in catching fish in these ponds, the banks of which are always strewn with snail shells, the former occupants of which, no doubt, are the intermediate host of the parasite. Patient also admitted that he often drank this water without boiling.



Schistosoma japonicum infection.

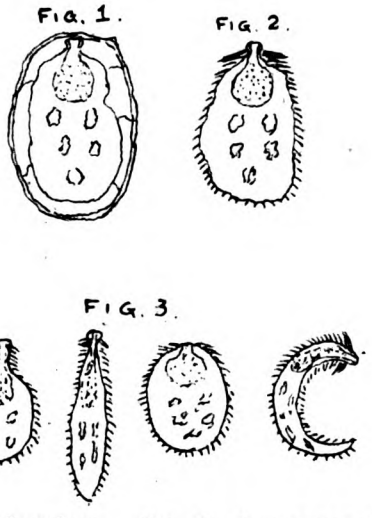
The boy gave a history of swelling of the legs and face about two years previous to admission to the hospital, and found that he could not do any considerable amount of work without great inconvenience on account of shortness of breath. Along with this he had bloody stools. At the time of admission he had, on an average, six of these stools in twenty-four hours, accompanied by prolapse of the rectum of some one and a half inches. His legs and face were swollen, and presented the appearance of a patient suffering from hook-worm infection. Spleen and liver not enlarged, as in our first case. The heart dulness was enlarged and the sounds muffled, except over the base, where there was a loud anæmic murmur. Conjunctiva and finger-nails were colourless.

The blood examination showed only 10 per cent. hæmoglobin. Differential count of the leucocytes showed:—

Polymorphonuclears	71	per cent.
Eosinophils	10	,,
Lymphocytes, small	11	,,
,, large	8	,,

Number counted, 112.

Poikilocytes and microcytes were numerous, with a fair number of megalocytes. No nucleated red cells were found.



Schistosoma japonicum. FIG. 1.—Appearance of egg as passed in fæces. Embryo inside. Cilia do not show on sharp focus. FIG. 2.—Embryo outside of egg, at rest. FIG. 3.—Shapes assumed by free embryo in recently voided fæces.

Patient entered hospital April 26th, 1906, and was at once given full doses of iron preparations, combined with strychnine and quinine, the latter in small doses. He improved rapidly, and on May 12th his conjunctiva was pink, and the hæmoglobin had increased to 35 per cent. The œdema of the legs and scrotum was still present, but the stools were only three a day, and the prolapse of the rectum was almost gone. There was no blood nor mucus apparent in the stool. Microscopic examination of the stool showed a few eggs of *Ankylostomum duodenale, Tricocephalus dispar*, and many of the ova of *Ascaris lumbricoides*; no eggs of the fluke under discussion were seen at this examination, although they had been found in previous examinations, and were also found subsequently. This fact is mentioned to show the necessity of repeated examinations in suspected cases, for if there is no point in the bowel that is ulcerating at the time, it is probable that no eggs will be present. It seems to be a well-established fact that the fluke does not thrust the eggs directly into the bowel but into the submucous tissue,

and that they act as a foreign body and eventually ulcerate out into the bowel.

June 8th. Patient was given 45 grains thymol in three doses and expelled eight hook-worms. Subsequent examinations showed none of the eggs of this worm present in the fæces.

June 16th. The patient left hospital. All œdema was gone, and there was no dyspnœa when patient walked about. Prolapse of rectum and dysentery had also disappeared, and patient declared that he was suffering no inconvenience whatever.

The microscope showed under a single cover-glass several eggs of *Schistosoma japonicum* and half a dozen embryos outside the shell moving their bodies vigorously, assuming all sorts of shapes, but making very little progression. The pressure on the cover-glass had been very moderate, and I am inclined to think that they had hatched out of the eggs after the stool was passed, about four hours previously, the weather being very warm. The movement of the cilia was very active, and the sac connected with the protuberance more clearly outlined. This was the first time I had ever seen movement in the embryo, but other examinations had been made in cool weather.

The third case is one seen by Dr. H. B. Taylor, of Ngankin, Anhuei Province, and I am indebted to him for the notes on the case, which has just been reported to the *China Medical Missionary Journal*. His case is interesting because there was no infection with the hook-worm, as was the case in all previous infections found in China, including Catto's, and it is of further interest because the patient was not œdematous, but on the contrary was much emaciated. The notes on the case are as follows :—

"The patient, a Chinese boy, aged 11, was a native of Wang Chiang Fu, about forty miles from Ngankin, near the Kiangsi border. He gave a history of chronic diarrhœa of many years' standing. The stools were bloody at times. Accompanying the diarrhœa there had been gradual enlargement of the abdomen and progressive weakness and emaciation. No history of œdema at any time.

"The boy was extremely emaciated, face, body, and extremities. Liver much enlarged, and three or four finger-breadths below the costal margin very tender, with rough nodular feeling on palpation through thin abdominal walls. Spleen also much enlarged, tender, but without nodular feeling. Intestines distended with gas.

"The first time the patient came to our dispensary the stools were formed and contained no blood microscopically. On examination, the ova of *Schistosoma japonicum* were found in small numbers, along with many of *Ascaris lumbricoides*. Subsequently the patient returned with dysentery. The ova were again found. This diagnosis was kindly confirmed by Dr. Logan, of Changteh, to whom I sent a specimen, and whose cases of schistosoma infection were reported in the *China Medical Missionary Journal* last year.

"At this time the boy was weaker, and more emaciated than at the previous visit. His abdominal symptoms remained as before. He remained three weeks in the hospital on iron and tonic treatment without material benefit."

It would thus appear that the disease under consideration is widely distributed in China, as it is now definitely settled that the three provinces, Fukien, Anhuei, and Hunan, each being separated from the other some hundreds of miles, furnish cases of the disease.

THE HÆMOGREGARINE OF MAMMALS (*H. BALFOURI*), AND SOME NOTES ON RATS.

By J. Burton Cleland, M.D. Ch.M.Syd..

Government Bacteriologist and Pathologist, Perth, W. Australia.

(From the Pathological Laboratory, Department of Public Health, Perth, W.A.)

It may be of interest to record, for Western Australia, the occurrence in a specimen of *Mus decumanus*, the "Norway" rat, of a hæmogregarine apparently identical with that referred to by Dr. Balfour in his article on the "Hæmogregarine of the Jerboa," in the Journal of Tropical Medicine for March 15th, 1906. In speaking of *H. balfouri* of the Jerboa, he says: "I have recently discovered what seems to be the same parasite in the mononuclear leucocyte of the Norway rat (*Mus decumanus*) in Khartoum. It is probable that it exists as a leucocytozoon in the rodents, but further observations are required."

The rat in which the leucocytozoon was found was one of many received and examined in this Laboratory in connection with plague work. Many of these were dead when received, but some were alive, and films of blood and smears from the organs were examined in a number of instances, and always when pathological conditions were present. In all the many preparations examined in this way this was the only instance in which the leucocytozoon was met with. Trypanosomes were frequently seen, but it is interesting to state that they were only encountered in those rats which were examined immediately after death. It is a remarkable coincidence that it was on the day after reading Dr. Balfour's article that the protozoon was discovered, and that neither before nor after that date have I again encountered it, though it could hardly have escaped notice had it been present. This particular rat, which had been kept alive in the Laboratory for about a fortnight, was given chloroform, and examined, when the only point noticed was a somewhat enlarged spleen. Only two blood smears were unfortunately obtained, both of which show fairly numerous beautiful examples of a leucocytozoon in the protoplasm of the mononuclear leucocytes. This parasite agrees perfectly with the figures and description in Dr. Balfour's article, and is, I think, undoubtedly the same. Sections were made of the liver and spleen, but no parasites were found in the fixed cells of these parts, though one was seen in a leucocyte in a capillary of the liver.

In the smears from the organs of this rat, made immediately after death, cocci and bacilli of several species were seen. It happened that at this time we lost a number of rats which we were keeping for experimental purposes. In those of them which were chloroformed while sick we found in smears quite a

number of organisms, though of course in these there could have been no *post-mortem* increase. Some of these were even bipolar, and suggested at first infection with plague. I could not account for some time for this apparent epizootic, in which were present during life so many diverse organisms. However, we found that in many instances the hind-legs were œdematous, and on examining the soles of the feet, ulcers of varying size were almost always found, swarming, of course, with bacteria. This condition was undoubtedly due to damp cages, and ceased when this defect was rectified. It suggests that even in their natural haunts this species of rat must suffer severely from the dampness accompanying floods and heavy rains, which possibly may have a checking effect on their numbers, and drive others to drier localities.

"C. R. Soc. Biologie," T. lx., pp. 349-350.

GLOBULAR RESISTANCE IN BILIOUS HÆMOGLOBINURIC FEVER.

Vincent, H., and Dopler, C., state that a chronic malarial subject cannot absorb quinine without provoking a crisis of hæmolysis.

His red corpuscles are constantly less resistant to quinine than those of healthy people, and become even less so during such a crisis. Treated with hypotonic solutions of sea-salt the corpuscles, constantly less resistant than those of the healthy, are even less so from the access of a crisis initiated by quinine.

After some days their resistance returns to the normal, and this enhanced resistance may be explained from the formation of new bodies in the blood as a sequel to the auto-hæmolysis. It may be noted that nine days after the crisis the serum of such a subject becomes less agglutinatory for its own corpuscles.

Searching for some explanation of the diminished resistance to quinine, the authors examine and reject the following hypothesis: That there are an insufficiency of "antisensibilisatrice," or an excess of cytase, or a lack of anticytase. We are left to suppose that the corpuscles are more fragile either from an insufficiency of the lepoid substances described by Overton or by a want of salts. In support of the latter supposition, they remark that, on the one hand, preventive injections of artificial serum in the patients may initiate a crisis of hæmoglobinuria, while on the other, the red corpuscles taken at the full crisis when their resistance to hypertonic solutions is at its least, may be rendered more resistant by prolonged contact with a less concentrated solution (1 to 100, about,) of chloride of calcium.

"Lancet," August 16, 1906, p. 438.

(SPIROCHÆTA DUTTONI.)

Stephens, Dr. J. W. W. The note concerns itself with methods of staining, especially with the demonstration of the flagellæ. The nitrate of silver method failed in the author's hands owing to the difficulty of cleansing the spirochætes from the albumucous blood plasma, even after repeated centrifuging and washing. He, however, obtained beautiful results by the following methods: The material was centrifuged and washed three or four times in normal salt solution. Films of the deposit were then made, and after mordanting, stained with gentian violet. The following forms were observed: (1) With terminal flagella no bipolar or peritrichous flagella were observed; (2) linked forms; (3) eviscerated forms, probably due to mechanical or chemical action. In many cases a sort of sheath was observed.

Business Notices.

1.—The address of the JOURNAL OF TROPICAL MEDICINE is Messrs. BALE, SONS & DANIELSSON, Ltd., 83-91, Great Titchfield Street, London, W.

2.—All **literary communications** should be addressed **to the Editors.**

3.—All **business communications** and **payments,** either for subscriptions or advertisements, should be sent **to the Publishers** of the JOURNAL OF TROPICAL MEDICINE. Cheques to be crossed The Union Bank of London, Ltd.

4.—The Subscription, which is **Eighteen Shillings** per annum, may commence at any time, and is payable in advance.

5.—Change of address should be promptly notified.

6.—Non-receipt of copies of the Journal should be notified to the Publishers.

7.—The Journal will be issued on the first and fifteenth day of every month.

Reprints.

Contributors of Original Articles will be supplied FREE with six copies of the Journal if a request accompany the MS. If reprints are required they will be supplied by the publishers, if the order is given with remittance when sending the MS. The price will be as below:—

50	Copies of four pages,		5/-;
100	,,	,,	6/-;
200	,,	,,	7/6;
50	Copies beyond four up to eight pages,		8/6;
100	,,	,,	11/-;
200	,,	,,	14/6.

One page of the Journal equals 3 pp. of the reprint.

If a printed cover is desired the extra cost will be for 50 Copies, 5/6; 100 Copies, 6/6; 200 Copies, 7/6.

Journal of Tropical Medicine

OCTOBER 1, 1906.

KITASATO'S SUGGESTION OF AN INTERNATIONAL CONFERENCE TO FIGHT PLAGUE.[1]

PROFESSOR S. KITASATO suggests that a national conference be formed to fight plague in India and South China. This opinion is the result of close observation of the epidemiology of plague ever since 1894, when Kitasato first discovered the plague bacillus in Hong Kong. He is of opinion that it is useless to fight plague by the present means, each nation individually enforcing quarantine laws, passing special regulations, disinfecting cargoes and people, and applying locally and generally all the paraphernalia attaching to modern hygienic measures. Kitasato is of opinion that the foci of the disease must be dealt with, and as at present India and South China are the chief seats of plague the battle has to be fought at these cradles of the disease. There can be no doubt that the Japanese and several nations in Europe blame British laxity of action for the present state of the world in regard to plague, and we have already, in this Journal,

[1] A paper read at the third annual meeting of the Philippine Islands Medical Association, March 3rd, 1906, and published in the *Philippine Journal of Science*, June, 1906. By Professor S. Kitasato, of the Institute for Infectious Diseases, Tokyo, Japan.

broached the question of interference of other countries in a matter which, as regards India at any rate, is wholly a British question. That interference has entered many minds there can be no doubt, and it comes to this: Are we to muddle through and allow things to drift on as they are doing, or wait for a request from other nations to take the matter in hand?

No doubt regard for British sensitiveness has restrained other Governments forwarding a request of the kind, but if plague recurs in India during the coming winter, to the extent it did during the winter of 1904-5, there are indications that a combined request may be forthcoming. Kitasato has publicly voiced the matter, and in his speech he asks the President of the United States of America to take up the matter. His words are as follows: "My suggestion only lacks a leader, and I see that the United States, one of the greatest nations of the earth, has such a leader in the person of its President, Theodore Roosevelt, who has already done so much for humanity and whose noble works are being admitted by the whole world." A better leader in a movement of the kind than the President of the United States it would be difficult to find; but surely, with the warning of what may be impending before us, it is possible to find a man or men of British nationality to forestall the interference and to rise to the occasion. What is to be done is another matter, and what is not being done in India is not perhaps so apparent; but that what we are doing is not satisfactory to people of other countries is becoming evident. Interference in Indian matters, military, political and medical, by the home Government, or by Parliament, has been, and is, a delicate question; and it is the desire to spare the feelings of Indian public servants generally that has deferred the enforcement, and not only the enforcement but even the direct suggestion, of many public questions which those outside India regard as requiring amendment. In the public press, in the meantime, the subject of "Our Failure in India" is being discussed. We have not failed in India, we have brought peace, order and security of tenure to some 300,000,000 of people where there would have been strife, bloodshed and chaos. Were Britain to have done nothing else, her rule in India has entitled her to the highest pinnacle of fame, and the men who have gained for her an unequalled place in history by their work in India are entitled to all the honour, fame, and consideration that can possibly be bestowed upon them. Still, according to other people, in regard to this question of plague epidemics, all is not as it should be, and we are submitted to the mortification of a Japanese scientist asking the President of the United States to undertake work which, in public opinion, we are not equal to. Kitasato states that plague, "however obstinate its ravages, could be fought and vanquished by the persistent efforts of man." The expenditure of "efforts, however laborious, the money, however vast, can be of no value unless they be accompanied by the application of scientific knowledge." According to Kitasato we are evidently lacking in the scientific knowledge necessary, and by allowing matters to drift we are inviting interference, which, when it comes, we will resent, and the sensitive occupants of the field in India will regard as an insult to their service.

Are we doing nothing? By no means; we have sent out commissions to investigate, but it seems to most people that the day for investigation is over, that the bacteriologist and the microscopist have done their work, and the *régime* of the practical sanitarian is required, not merely detailing for plague duty several already overworked men of the Indian Medical Service, but the temporary creation of an army of workers, not in hundreds but in thousands, to deal with plague. As Kitasato says, the money spent for this temporary work would be less than the plague expenditure incurred by the world at the present moment from quarantine hindrances, disinfection, expenses, loss of trade and loss of life. Unless a step of the kind is taken, and that speedily, we will have to bear the chagrin of the interference, justifiably or unjustifiably, of other nations coming forward and requesting us either to mend our ways and eliminate plague, or to allow them to do the work we are avowedly incapable of. J.C.

BRITISH MEDICAL ASSOCIATION MEETING AT TORONTO, AUGUST, 1906—ABSTRACT OF PROCEEDINGS.

Obstetrics and Gynæcology.

President: Dr. W. S. A. Griffith (London.)

Professor A. H. Wright (Toronto) introduced the subject of "Concealed Accidental Hæmorrhage in the Latter Part of Pregnancy, before the Effacement or Dilation of the Cervix." He pointed out that the patient in such cases suffered more from shock than from actual loss of blood. The treatment recommended was morphia to the extent of 1 grain in one hour if severe shock threatened. Dr. W. S. A. Griffith stated that dangerous hæmorrhage, of the nature referred to by Prof. Wright, was very rare; when, however, such occurred, in cases in which the cervix was tough and undilatable section of the uterus (vaginal) should be done; in multiparæ, when the os and cervix were capable of dilatation this should be done along with bipolar version. Dr. Temple (Toronto) and Dr. Murdoch Cameron (Glasgow) condemned Cæsarean section for an ailment of this nature, nor was vaginal section of the cervix necessary according to Dr. Temple. Dr. Cameron stated that he had never seen a death from concealed accidental hæmorrhage in the latter part of pregnancy.

Chronic metritis and arterio-sclerosis of the uterus were discussed by Drs. Gardner and Goodall (Montreal). In uterine arterio-sclerosis, Dr. Barker said that nothing short of hysterectomy was of any use.

Dr. A. E. Giles (London) described the results of 146 consecutive cases of ventri-fixation of the uterus; the benefits in many instances were stated to be most marked. This subject was discussed by Drs. Bovée (Washington), Dudley (Chicago), Gardner (Montreal), Gilliam (Ohio), Temple (Toronto.)

"Changes in Uterine Fibroids, after the Menopause, with Reference to Operation," was dealt with by Dr. C. A. L. Reed (Cincinnati). He advocated removal of uterine fibroids occurring about the time of the menopause. This conclusion was refuted by Dr. J. T. W.

Ross (Toronto), who stated that a fibroid was merely an outgrowth of the muscular tissue of the uterus, and cancerous development in tumours of the kind was rare. Even in young married women small uterine fibroids might exist without causing trouble, and that their removal could not be undertaken without serious danger to the patient. The comparative harmlessness of fibroids, in proportion to the number of actual cases, was insisted upon by Dr. Byford.

Dr. H. L. Reddy (Montreal) brought forward the indications for Cæsarean section, other than in pelvic deformities and tumours.

"The Appendix Vermiformis in Relation to Pelvic Inflammation" formed the subject of a paper by Dr. Helme (Manchester). He discussed the association of inflammation of the appendix and pelvic organs, believing that contiguity rather than continuity of structure was the explanation of the association. Appendicitis, according to Dr. Helme, is a frequent source of dysmenorrhœa and its associated mucous colitis, but the association of appendicitis with pelvic disease is the exception and not the rule. The appendix, Dr. Helme regards, not as a vestigial structure but as a differentiated part of the intestinal tract which plays a high and important part in digestion. He condemns the removal of the healthy appendix during operations for pelvic disease. Dr. Lockyer (London) dealt with the relationship of appendicitis to pregnancy, and the treatment of the conditions when the two are combined.

Prof. Murdoch Cameron (Glasgow), in a paper entitled "Antistreptococcus Serum in Puerperal Septicæmia," advocated its use in puerperal fever in which there is but little laceration of the soft parts, but condemned its application as useless when the fever was due to traumatism.

The subject of "Eclampsia" was introduced by Dr. Evans (Montreal); he referred to Edebohls' treatment for eclamptic anuria by renal decapsulation. Lumbar puncture, introduced by Helme, had not proved successful. Dr. Temple (Toronto) favours blood-letting, the use of morphia, and where the cervix is dilatable the induction of labour in the treatment of eclampsia.

Section of Dermatology.

President: Dr. Norman Walker (Edinburgh).

"The Influence of Light-hunger in the Production of Psoriasis" was introduced by Dr. J. N. Hyde (Chicago). He said that one statement was that psoriasis never affects the lower animals because their skins are exposed to light. Another, that were psoriasis in man due to light exclusion the number of persons attacked would be few: the parts of the body attacked coincide with those least exposed to daylight; the disease should be localised in light-excluded parts; the rational treatment would seem to be that by illumination. Dr. Dühring did not agree with Dr. Hyde as to the etiology of psoriasis; it is certainly not parasitic, and the treatment by local measures are well-nigh useless, internal treatment presenting the only hope of relief. Dr. L. D. Buckley (New York) said local treatment was inadequate, and that the altered condition of the system permitted the growth of organisms. Drs. G. H. Fox (New York) and W. T. Corbett (Cleveland) remarked on the apparent immunity of the Negro Race. Dr. Gilchrist (Baltimore) believed psoriasis to be of parasitic origin, and advocated the use of X-rays in the treatment of the disease.

"Bullous Eruption" was discussed by Dr. J. C. Johnston. He contended that bullous eruptions were autotoxic in origin, and required treatment by diet, laxatives, diuretics, exercise, hot-air baths and pilocarpin.

Dr. Graham Chambers gave a clinical demonstration of the treatment of ringworm by means of a preliminary X-ray epilation before applying the usual remedies.

"Errors in the Treatment of Cutaneous Cancer" were discussed by Dr. A. R. Robinson. He said no fixed rule could be applied to the treatment of these ailments; excision is unsuited for cancer on the skin of the face; X-ray treatment is of no value where the deeper structures are involved, and ought to be confined to certain specific forms; when X-rays are employed the superficial cutaneous layers and nodules ought to be removed by applying X-rays. Dr. R. W. Taylor (New York) maintained that coincidently with primary local syphilis the whole system becomes affected by way of the blood rather than by way of the lymphatics.

"The Wrong and the Right Use of Milk in Certain Skin Diseases" was the subject of a paper by Dr. L. D. Bulkley. In cases of acne, eczema, and urticaria he found milk, given one hour before meals, when the contents of the stomach were alkaline, was absorbed without previous caseation, and proved beneficial; a vegetable diet should be combined with the milk treatment.

MALARIA IN GREECE.

Liverpool School of Tropical Medicine.

Sir Alfred Jones, K.C.M.G., gave a lunch yesterday, at the University Club, to Dr. Savas, of the University of Athens, Physician to H.M. the King of Greece. Owing to ill-health Sir Alfred was unable to attend, and in his place the Lord Mayor of Liverpool (Alderman J. Ball) presided. Among those present were: Lord Mountmorres, Professor Boyce, Professor Ross, Professor Carter, Professor Bosanquet, Dr. Caton, Dr. Hope, Dr. Utting, Dr. Todd, the Rev. Arch. Gabriel, the Hon. J. L. Griffith (U.S. Consul), Mr. T. H. Barker (Secretary, Liverpool Chamber of Commerce), and others. A telegram was read from Sir Alfred Jones thanking the Lord Mayor for taking the chair. A letter was received from Mr. Mataxas, Minister for Greece in London, thanking the Liverpool School for their help in the movement for suppressing malaria in Greece.

On the proposition of the Lord Mayor, the loyal toast and the health of the King of Greece were honoured. The Lord Mayor then proposed the health of Professor Savas.

Professor Savas, in responding, said that he was sorry he could not speak the English language sufficiently well to express all he wished, but he desired

to say how he thanked H.R.H. Princess Christian for her assistance to the cause he represented, Sir Alfred L. Jones for the great help he had given the Liverpool School of Tropical Medicine, and Professor Ronald Ross. The interest shown in this country in the movement for the abolition of malaria in Greece was one of many instances of the kindness that Great Britain had always shown to his country.

Dr. Ronald Ross then gave an address dealing with malaria in Greece. He explained that on the invitation of the Lake Copias Company, Limited, he was sent out to Greece at the instance of the Liverpool School of Tropical Medicine to investigate malaria in that country. He went to Greece last May, and found such a condition of affairs as decided him to report to the Liverpool Tropical School and to the city generally. The way to investigate malaria was to examine the condition of the school children, and in the course of this work he found in one village 38 children out of 80 affected; in another 13 out of 40; in another 25 out of 50, and in a mountain town 16 out of 100. In the city of Thebes the proportion was only one in 50. The general statistics applying to the whole country showed that out of a population of two and a half millions roughly there were about a quarter of a million cases a year. There were 250,000 cases of malaria per year, and the deaths were about 1,760. Last year there was a bad epidemic, and the cases amounted to 960,000, the deaths numbering 5,916. On the average there had been, roughly speaking, two attacks of malarial fever for every five persons in the country last year. Of such a state of things they could have no conception in this country, for it was not a case of having the disease once, like measles or scarlatina, but the trouble came week by week and month by month. It was evident that the ancient civilisation of Greece was checked by some cause, and he was of opinion that the cause was the spread of malaria. The disease was probably introduced or reinforced by the natives of Asia, introduced by their Greek conquerors. They had a modern instance of the same sort of thing in the Mauritius in 1866, when the disease swept round the coast and ruined the place. Probably the event took place about the time of Pericles, and it must have done a great amount of harm. In considering the causes of the rise and fall of nations they were apt to overlook the influence of disease. The movement for the suppression of malaria was supported in influential quarters, and they hoped to obtain the support of the Liverpool people.

Mr. W. Watson Rutherford, M.P., said that Liverpool, with its associations all over the world, should take cognisance of a proposition laid so influentially before them. Very valuable work had been given in the direction of checking malarial disease by Dr. Ross, Prof. Boyce, and Dr. Todd.

Mr. Daniel Steele, General Manager of the Lake Copias Company, Limited, expressed his appreciation of the help extended to Greece in that matter, and his conviction that satisfactory progress would be made.

The Hon. J. L. Griffith, U.S. Consul, also spoke, and said that Liverpool had now the opportunity of paying part of the debt which all civilisation owed to Greece.

On the proposition of Lord Mountmorres the health of the Lord Mayor was drunk and the proceedings ended.—*Liverpool Courier*, September 18th, 1906.

———

NOTES ON PLAGUE IN INDIA.

Rat Destruction.

The difficulties connected with rat destruction are many. One is the religious difficulty, as amongst several communities taking of life of any living thing is a strict tenet to be observed. Another, however, is more quaint; it seems that some people object to the rats being destroyed because they cannot then be warned when plague threatens; death amongst rats being a sure sign that plague will attack human beings. So far has this curious form of prophylax is seized upon the minds of natives that the British resident in Mysore finds it necessary to "dissipate the idea that it is useful to have rats in order that their dead bodies may give warning of the presence of the disease."

In the Punjab the decrease of mortality from plague was less by 300,000 during the first six months of 1906, compared with the corresponding period of 1905. To the destruction of rats is this fortunate result chiefly attributed.

Poona is suffering from a severe recurrence of plague. On September 11th and 12th, 268 persons in the city died of the disease.

Monkeys and cats are reported to be suffering from plague in some districts of the United Provinces.

Clemesha, W. W., Captain I.M.S., in an article in the *Indian Medical Gazette* of September, 1906, on "An Account of Plague in Bengal," states: "That for the spread of plague the presence of large numbers of rats is the chief factor; insanitary houses are also an element in the spread, but chiefly from the fact that such houses are obviously an abode for rats." People engaged at certain trades seem to be especially liable to plague, but when these come to be looked into it is found that it is not the trade itself that is the cause, but the environment in which the trade is carried on, that determines the presence of the disease. It is almost always the village shopkeepers who are first attacked by plague, and these men conduct their work in dark, rat-infested godowns, sheds, and grain-stores. So strong is Captain Clemesha's belief in the infecting power of the rat that he states: "A house so constructed as not to be suitable for rats to live in and not containing any food to attract rodents, would probably remain non-infected unless a case of pneumonic plague was placed in it." In Eastern Bengal plague does not now prevail, nor has this province at any time during the past ten years suffered severely from plague; the reason may be, that in this part of Bengal the villages are long, straggling lines of houses; each house usually is buried in a thicket of bamboos and rank vegetation in its own compound and at some distance from the neighbouring houses. Rats are not so plentiful in houses of this type as in the closely packed mud houses met with in such districts as Bihar, where plague is rife.

Immediate Incision into Plague Glands.

Nesfield, V. B., Captain I.M.S., in the *Indian Medical Gazette* of September, 1906, argues in favour of early incision, in cases of bubonic plague, with the object of preventing toxin absorption. He states that in plague, as in other septicæmic infection, the specific organisms in the lymphatic gland are engaged in rapidly elaborating toxins which are readily taken up by the lymphatic and vascular systems and so produce a condition of poisoning. Within the gland, in time, however, the organisms themselves, owing to their numbers, cannot be accommodated in the space, and gaining the lymph and blood streams cause septicæmic lesions. The presence of the toxins in the blood tend to lessen the power of the resistance of the blood to the organisms, so that the longer the toxins are being absorbed the greater the ease with which the organisms gain access to and ascendancy in the blood. To prevent the further absorption of toxins, and subsequently of organisms, Captain Nesfield recommends that, where possible, every superficial gland should be opened with as little delay as possible. The gland should not on any account be excised; a simple incision should be made deeply into the substance of the gland, so that the toxic serum and plague organisms may have free exit, but the cellular tissues and periglandular lymphatics should not be disturbed. After opening the gland Captain Nesfield pours strong tincture of iodine lotion, about 2½ per cent., into the cut surface, and foments the part by lint soaked in the same fluid.

Reviews.

The Extra Pharmacopœia: Martindale and Westcott. Twelfth Edition. London: H. K. Lewis, 136, Gower Street, London, W.C., 1906.

A revised edition of this useful publication is to hand. It is not, surely, necessary to dwell upon the excellence of this well-known book. Every medical man must have it at his elbow if he hopes to be cognisant of all that is most recent in therapeutics and the rational treatment of disease. The present volume extends to 1045 pages, and there is not a page too many, nor a line that can be spared. The labour, the care, the precision and the literary efforts involved in the production of the "Extra Pharmacopœia" have always excited our admiration, and the additions to this, the twelfth edition, still further bear out the reputation of its predecessors. We have frequently, when new drugs are forwarded to us from tropical countries, especially those in use by the natives, consulted Dr. H. Harrison Martindale concerning them, and in almost every instance he has been able to point out to us that the "new" plant or drug is dealt with in the "Extra Pharmacopœia." The chapters on Organotherapy, on Analytical Memoranda, and the Therapeutic Index of Diseases and Symptoms are special features of the twelfth edition, and we cordially acknowledge the debt we owe to the authors, W. Harrison Martindale, Ph.D., and W. Wynn Westcott, M.B., D.P.H., for the services they have rendered to British medicine by their arduous labours.

Correspondence.

THE TRUTH ABOUT BERI-BERI.

To the Editors of the Journal of Tropical Medicine.

Sirs,—You will perhaps allow me a small amount of your valuable space to acknowledge the whole-hearted acceptance by Dr. H. Wright in your Journal of August 15th (vol. ix., p. 246, 1906) of the truth of the observations I have set forth (*Journal of Hygiene*, vol. iv., p. 112, 1904, and *British Medical Journal*, vol. i., 1904).

Whilst he substantiates my observations so strongly as actually to claim them as his own, there will be many who will regret with me that he did not give public renunciation of the statements he had made ("Studies from the Institute of Medical Research," vol. ii., 1902) some time during the two years or so that elapsed between our several publications. This would have saved me from the unpleasant task of correcting some of his errors of fact and inference in detail, a task which two well-known men of science strongly urged upon me as a "matter of public duty."

I remain, Sirs, yours, &c.,

Hereford, *September*, 1906. Herbert E. Durham.

Drugs and Remedies.

Dr. Prendergast's diarrhœa pill:—

℞	Bismuth salicylate	grain 1
	Salol	,, ½
	Calomel	,, $\frac{1}{40}$
	Camphorat. tinct. of opium ...	mins. 2
	Aromat. chalk powder	q.s.
	Cinnamon oil	q.s.

For one pill.

Foramint (*Medizinische Klinik*, No. 16, 1906).—Daus, Dr. S., of Berlin, speaks highly of the disinfectant action of formic aldehyde on mucous membranes. Hitherto the use of even very dilute solutions of formic aldehyde, owing to its extreme irritability, has prohibited its use, but by combining it with milk sugar this difficulty has been partly overcome. It is as a disinfectant for the mouth, fauces, tonsils and pharynx that this combination, named foramint, in the form of lozenges, has come into use. In acute follicular tonsillitis, mumps, quinsy, diphtheria, middle ear disease, foul tongue and breath, and as an oral disinfectant generally, foramint would seem to be more efficient and more practically useful than attempts at gargling or swabbing out the throat, which are often well-nigh impossible and always imperfect. We have tried foramint, and find the remedy to be both pleasant and efficient in mouth and throat affections.

Notes and News.

Thankful for Small Mercies.—From a recent circular: Church Missionary Society, Medical Mission, Yezd, Persia . . . . The hospitals are now, thanks to God's blessing on our work, so crowded as to be very insanitary, and the Women's Hospital is totally unsuitable for its purpose.

Dr. S. C. Legge, Surgeon of the B. I. steamer "Jelunga," has died in the General Hospital, Calcutta, of acute pleurisy, at the early age of 35 years.

How not to Do It.—At a recent meeting of the Bombay Corporation, during a discussion on the campaign against rats, Mr. Todd said he was assured by his Hindu friends that they perfectly realised the necessity of getting rid of rats. They set traps for them and caught them, but as they could not kill them, they let them loose in drains and open spaces.

A Correspondent of the *Indian Pioneer*, signing himself "Medico," complains of the absence of all practical teaching of Midwifery in the University of Lahore. It must be confessed, however, that the peculiar social system of India renders attendance of students in actual cases of labour almost impracticable. It is only as a last resource, in desperate cases, that a male practitioner is ever called in, and it is practically certain that even such cases would be left without competent assistance altogether, if students were allowed to accompany the practitioner called in. During twenty years' practice in India, though often called upon to perform craniotomy and other obstetric operations, the writer never had the opportunity of attending a normal labour in a native, and under such circumstances it is difficult to see how practice in this department can be arranged for students. This may be unfortunate, but, it is to be feared, is unavoidable.

The Health of Bombay.—A Bombay message to a contemporary says: The condition of public health in Bombay continues to be unsatisfactory. The mortality last week was only a hundred short of double that of the corresponding week of last year. The main cause of this exceptional unhealthiness is the prevalence of cholera and choleraic diseases. There were 119 deaths from cholera — the highest total reported during this epidemic—and 99 from diarrhœa. But although the figures are higher than before, there are signs that the epidemic is about to wane, and unless abnormal conditions supervene the presence of the disease in our midst should not be protracted much longer. The unusual continuance of cholera in the city at this season has brought the water supply under suspicion, but these apprehensions are not founded on fact. The disease is spread all over the city, and local outbreaks have shown themselves amenable to preventive measures; so that although the water supply may in parts be liable to pollution, this cannot be the source of infection. Undoubtedly the food and milk supply of the people at this time of year has a good deal to do with the prevalence of diarrhœa, and that predisposes to cholera when the latter disease is about. The carelessness of the mass of the population in exposing their food and milk to flies and dust is also notorious, and this is a serious factor in the spread of infection.—*Pioneer Mail*, August 10th.

Major Ernest Roberts, I.M.S., has just brought out an extensive work on enteric fever in India, published by Thacker, Spink and Co., Calcutta. As yet we have only before us a highly eulogistic review in the *Indian Pioneer*, a lay paper, which, however, frequently notices scientific works on subjects which, like the present, are of high public importance.

As Secretary to the Sanitary Commissioner and Statistical Officer to the Government of India, Major Roberts has had exceptional opportunities of studying the incidence of typhoid, so that the work can hardly fail to be of great practical value.

Major Roberts shows that typhoid for many years has been, and is still increasing, and this in spite of almost every cantonment having been supplied with excellent water. Added to this, enormous improvements have been accomplished in the care and cooking of milk and other articles of food, and in the housing and well-being of the soldier, in numberless ways, and all, as far as enteric is concerned, absolutely to no purpose. One thing alone has remained unchanged, and that is the official system of conservancy, which is still on the "trenching system." It is refreshing to find this pernicious military medical fetish attacked by one of the Inner Simla Circle, and it is a healthy sign of the times that such an one should be able to venture to attack it; for certainly, until lately, the heretic who dared to attack the sacred trenching system would have been hardly likely to stay long at Simla.

We trust that the Indian Government will see its way to adopt Major Roberts' suggestion of water carriage to septic tanks, as the present plan of distributing typhoid dust, by spreading the infected night-soil out in the sun, with a thin layer of dust over it, is so against rhyme and reason that it is marvellous that it should have been so long supported by the medical authorities in India.

Plague in Calcutta.—Dr. Pearse's report on plague in Calcutta during the year ended June, 1905, was submitted in August last. Dr. Pearse establishes a number of striking conclusions concerning plague as it operated in this city. He shows that the alleged comparative immunity of women is a delusion. The proportions of men and women attacked are precisely the same as the proportion of men and women in the total population. If fewer women are attacked this is because there are fewer women than men. Another lesson from the experience of Calcutta is that the danger of infection by personal contact with plague patients is much less than has been generally supposed. The great majority of plague cases occurred in separate houses, that is, plague patients did not infect other inmates of the dwelling. The result of Dr. Pearse's direction of the anti-plague campaign has been a flood of light thrown on the causes of death in Calcutta. In many cases, at ordinary times, no medical man is in attendance and the cause of death is not ascertained. The special arrangements in connection with plague have dispelled this ignorance, and revealed an unsuspected prevalence of phthisis, tetanus, and a number of obscure diseases.—*Pioneer Mail*, September 7th, 1906.

An Appeal from Western China.—Bishop Cassels has written from Tao-ning, Western China, a letter on behalf of missionary work in China, in which he

says: "It is many years since we have been so destitute of any medical help in this station and district as we are just now. Even though we had no doctor, we nearly always had some qualified nurse and someone who could undertake dispensary work; but now we are absolutely without any help of this kind, and the workers are so busily occupied that in case of any sickness requiring nursing we should be in a very difficult position." Those who would like to hear further on this matter should apply to Miss E. Van Sommes, Cuffnels, Weybridge. — *The Hospital.*

THE NUWARA ELIYA'S DISTRICT MEDICAL OFFICER.—Dr. Frank Grenier's *selection* as Ceylon's first representative to the London School of Tropical Medicine may be regarded as a compliment to the District Medical Officer of Nuwara Eliya, who has the reputation at the sanatorium of having proved a worthy successor to the late Dr. W. G. Woutersz. Dr. Grenier does not leave for Europe till next year.

BEHRING'S REMEDY FOR CONSUMPTION: TULASE.—The material produced by Professor Behring for the cure of consumption, "tulase," consists of a clear liquid prepared by treating tubercle bacilli with chloral. A toxin, differing from Koch's, has been obtained from the tubercle bacillus, which is stated to continue the process of immunisation where Koch's tuberculin leaves off. Although tolerance to tuberculin may be established, persons so treated are not immune against the tuberculosis caused by Koch's tubercle bacillus, and it is to continue the beneficial effects of Koch's tuberculin that Behring has been striving after. Tulase contains the bodily substance (somatic) of Koch's bacillus. It may be introduced intravenously, subcutaneously, or by way of the stomach. The best result is obtained when tulase is given in the form of an immunising milk by the stomach. Tulase is not on the market, and will not be so, until the exact dosage and methods of exhibition are positively determined.

Personal Notes.

INDIAN MEDICAL SERVICES.

Arrivals Reported in London.—Captain F. Wall.

Extensions of Leave.—Major T. W. Irvine, study leave, July 1st to 7th, 1906; Captain V. E. H. Lindesay, 6 m. furlough; Captain D. C. Kemp, 9 d. extraordinary leave; Major A. Street, study leave, May 16th to August 15th, 1906; Captain H. Meakin, 6 m. medical certificate; Colonel R. Macrae, 3 d.; Captain L. Reynolds, 6 m. medical certificate; Lieutenant J. W. H. Babington, 3 d.

Permitted to Return to Duty.—Lieutenant-Colonel A. Milne, Major T. C. Clarkson, Major H. Austen Smith, Captain A. T. Pridham, Colonel R. Macrae, Lieutenant-Colonel O. H. Channer, Captain G. Tate, Captain R. Bradley, Nursing Sister Miss M. E. Gray.

Postings.

Captain Hunter, services placed at disposal of Government, United Provinces.

On return to India from leave, Lieutenant-Colonel Cunningham becomes Civil Surgeon of Umballa, while Lieutenant-Colonel Adie returns in the same capacity to Ferozepur, and Lieutenant-Colonel Coates to Lahore.

Lieutenant R. T. Collins, R.A.M.C., to hold additional civil medical charge of Roorki.

Surgeon-General Trevor is confirmed as P.M.O., Western Command, and Surgeon-General Slaughter to be P.M.O., Eastern Command, *vice* General Gubbins, appointed P.M.O. in India.

Home Department.—The services of Major Macrae and Captains O'Neill, Scroggie, and Rogers are temporarily placed at the disposal of the Madras Government.

The services of Captain Justice are lent permanently to Madras.

The services of Captain Roberts are lent temporarily to the Punjab, and the services of Captain Bamfield are replaced at the disposal of the Commander-in-Chief.

Civil Assistant Surgeon Rai Sriput Sahai to be Civil Surgeon, Hamurpur.

Promotion.

Captain Vivian Boare Bennett, M.B., F.R.C.S., to be Major.

COLONIAL MEDICAL SERVICE.

Dr. W. B. Thain, Medical Officer of Ashanti, Gold Coast Colony, becomes Acting Cantonment Magistrate at Kumasi in place of Major T. A. Pamplin Green, who has arrived in England on six months' leave.

PLAGUE.

PREVALENCE OF THE DISEASE.

			Cases.	Deaths.

Hong Kong.—One case of plague during week ended August 26th. Clean Bill of Health issued.

Australia.—No cases of plague since June 30th. Rodents found infected in Brisbane in August.

South Africa.—No plague since November, 1905 Rodents occasionally found infected in East London.

Prescriptions.

MALARIA—ADMINISTRATION OF QUININE HYPODERMICALLY.

T. C. Wilson, in his "Text-book of Applied Therapeutics," gives the following preparations for hypodermic injection in malaria:—

℞ Quin. hydrochlorat ... ... grains 7½
Aquæ destil. ... ... mins. 15
For one injection.

℞ (Köbner's formula).
Quin. hydrochlorat ... ... grains 8 to 15
Glycerini ... ... mins. 30
Aquæ destil. ... ... mins. 30
For one injection; administered lukewarm.

℞ (When given combined with antipyrin).

Antipyrin	grains 6
Quin. hydrochlorat	grains 15
Aquæ destil.	mins. 30

For one injection.

℞ (Chlorhydrosulphate of quinine is recommended by Wilson).

Quin. chlorhydrosulphat ...	grains 7½
Aquæ destil.	mins. 15

For one injection.

℞ Sulphate of quinine may be administered when combined with tartaric acid.

Quin. sulphat.	grains 15
Acidi tartarici...	,, 8
Aquæ destil.	mins. 150

Recent and Current Literature.

A tabulated list of recent publications and articles bearing on tropical diseases is given below. To readers interested in any branch of tropical literature mentioned in these lists the Editors of the Journal of Tropical Medicine *will be pleased, when possible, to send, on application, the medical journals in which the articles appear.*

"Ann. d'Ig. Sper.," T. xvi., p. 199.

On the Effect of Passage through the Intestines of Earth-worms or Soil Germs.

Guargena, G. With rather unimportant exceptions, the author finds that the intestinal flora of the worms is the same as that of the soil, and that bacilli, whether found naturally, or artificially added to the soil, are but little affected by passage through the intestine of the worm. A strain of *B. prodigiosus*, however, increased in virulence while *Staphylococcus citreus* attenuated rapidly. The author, however, demonstrates the important fact that worms can carry germs to considerable distances and infect the soil of their new resting place.

"Malaria in Tonkin and Northern Assam," pamphlet, 11 pages, with Titles and Charts.

Salanoire, M., undertook an extended enquiry to clear up certain points in the etiology of malaria in these regions.

His results are combined into a table giving (1) for each station the proportion of ♀ anophelinæ to 100 culicinæ for each month of the year; (2) two curves showing the average annual proportion of the two sub-families and the incidence of primary malarial attacks; and (3) a curve showing the monthly proportion of *Anophelinæ* and *Culicinæ* for all posts taken together.

Admitting, as indeed the author does, that curves of this sort cannot be taken as having an absolute value, it is obvious that except in two posts, there is a definite relationship between the commonness of *Anophelinæ* and the incidence of malaria. At Ha Gian, one of these exceptions, *Anophelinæ* are very scarce, though it is the most malaria-stricken place in Tonkin. The surrounding country, however, swarms with *Anophelinæ*, and Salanoire therefore concludes that the disease is contracted not at the post itself, but on the way to it. The other exception, Quang Yen, on the other hand, is regarded as a healthy station, so much so, indeed, that it has been chosen as the site of a convalescent depôt, but nevertheless the proportion of *Anophelinæ* is enormous.

Salanoire would explain this by the fact that most of the malaria cases are under treatment and so would rarely infect the insects, but it is obviously possible that it may be a matter of the species of anopheline which is common there. *Anopheles rossi*, for example, is rarely if ever a carrier of malaria. The author then gives some details of the forms of parasite observed, and clearly holds the theory of the specific unity of malarial parasites, and finally deals with the subject of bilious hæmoglobinuric fever, which he considers quite distinct from the paroxysmal hæmoglobinuria of Europe.

"Annales del Circulo Medico Argentino," 1905, p. 375.

Streptothrix Maduræ.

Greco, Nicolas. From the excellent clinical account given by the author of a case originating in an inhabitant of the Province of Santa Fé, in the Argentine Republic, it appears fairly certain that "Madura foot" occurs in that country. The patient had an inflamed lymphatic gland in the corresponding thigh, and Senor Greco isolated from the pus cultures of an organism, which he believes to be identical with Vincent's *Streptothrix* (*Discomyces*) *maduræ*.

"Ann. d'Ig. Sper.," T. xvi., p. 251.

A Case of Hæmogregarina Bovis.

Martoglio and Carpano. Working at the production of a serum for cattle plague, the authors found in a slide left over night some peculiar bodies which exhibited certain staining reactions.

Nothing similar could be found in the blood of the calf that had yielded the blood from which the slide was made, and the blood injected into a sheep produced no infection. But the structures are, nevertheless, described under the above name. Under the circumstances the authors would have been better advised had they refrained from naming these problematical appearances. It is very possible that a species of Hæmogregarine may be found at some future period in the blood of cattle, and as the identification of any such find with this should be called *Hæmogregarine bovis* is clearly out of the question; a very eligible name has been occupied to no better purpose than the gratification of the passion for species-making.

"Ergeln. d. allgem. Path. und Pathol. Anal. des Menschen und der Tiere," T. x., p. 305.

The Trypanosomiases from the Standpoint of General Pathology.

Sauerbeck, Ernst, whose recent work on the pathological anatomy of this disease specially fits him for the task, here follows out his subject in a sound and competent manner.

After a brief account of the morphology and phylogeny of the trypanosomes, the author first considers the non-pathogenic members of the group, such as the *Tryp. lewisi* of rats and *T. paddæ*, Laveran and Mesnil, and then proceeds to the consideration of the pathogenic species. Most space is devoted to *T. brucei* as in all respects the best known member of the group, and includes an able criticism of the views of Bradford and Plimmer (plasmodial and amœboid forms, &c.), and of Prowazek's sexual forms. Convenient tables are given of the liability to, and duration of the malady in different animals, as well as a good *résumé* of his own researches.

Surra, Caderas, and Dourine are treated in a few pages, and human trypanosomiasis occupies but three; Indian fevers and the Leishman-Donovan bodies are treated with greater minuteness, and he shows how Leishman's original theory has had to be modified by the work of Major L. Rogers, though he does not consider that the latter has demonstrated the presence of true trypanosomes in his cultures. He compares the examples of *Piroplasma donovani* with that *Halteridium* or *Hæmoproteus noctuæ* of Schaudinn.

He points out that the trypanosomes at present include a great variety of types, the extremes of which are the true trypanosomata, which are exclusively extracellular parasites, and the *P. donovani*, which is always intracellular, and pre-

dicts that subdivision of the group will be necessary. A short appendix on methods of staining is included.

"Zeit. chir. f. Hyg.," T. lvii., p. 512.

The same author gives an account of some work supplementary to his recent study of experimental trypanosomiasis, in which he demonstrated the capital importance of the macrophages in the destruction of trypanosomes. He now describes the appearances in the bone-marrow of a moribund guinea-pig infected with nagana, and of a rat with caderas, and confirms Prowazek's discovery of the presence of trypanosomes in the interior of typical polynuclear leucocytes.

"Lancet," September 22, 1906.

BLACKWATER FEVER DUE TO QUININE.

The journal comments on a case of the sort reported by Dr. A. D. Ketchen in the *South African Medical Record*.

The patient had suffered from malaria in East Africa, and recovered under quinine. Six months later, at Cape Town, he fell into ill-health and suffered from dysentery. Under these circumstances the malarial symptoms occurred, and on quinine being again exhibited he developed hæmoglobinuria, and frequent subsequent attempts to administer the drug—intentional and accidental—showed that the urine blackened within a very short time, even after such small doses as $\frac{3}{4}$ grain.

The *Lancet* appears to regard this as "conclusive"; but though no one questions that quinine may cause hæmoglobinuria in susceptible persons, as such cases are not very rare, it is quite a different matter to assume that toxic symptoms of this sort are identical with blackwater fever, and the readiness and rapidity with which the patient recovered from repeated attacks as soon as quinine was withheld appear to point to quite an opposite conclusion.

"Lancet," September 15, 1906, p. 718.

ANKYLOSTOME PARASITISM AMONG THE NATIVE WORKERS IN THE TRANSVAAL.

Posnet, W. G., records that as far back as 1904 he met with a case of ankylostomiasis in a native prisoner in the Johannesburg Gaol. He has since, as pathologist to the Johannesburg Hospital, investigated the prevalence of the disease amongst native African miners on the Rand, and found the ova of the parasites in the stools of 32 per cent. of the cases examined. Although not commonly a direct cause of mortality, he regards the disease as a potent cause of disability and diminished resisting power, and points out the danger to white miners, suggesting, indeed, that the outbreak in our Cornish mines investigated by Haldane and Boycott in 1902 was imported from South Africa, by Cornish miners who were driven to seek work at home by the late war. He has found the parasite in African miners coming from so many parts of British and Portuguese South Africa that he believes the disease to be very widely spread among the native tribes, and points out the danger to those engaged in the mining industry, white and black alike, unless suitable measures be taken to cope with the spread of the disease.

"Ann. Soc. de Méd. de Gaud.," T. xxxv., p. 231, and "Arch. Parasitologie," T. x., p. 160.

CONTRIBUTION TO THE STUDY OF TRYPANOSOMIASIS: THE PROLIFERATION OF TRYPANOSOMES IN THE ORGANS.

These observations were carried out on rabbits infected with *Tryp. brucei*, in which animals the disease runs a rather protracted course, and but few parasites are to be found in the circulation, so that the estimation of the numbers found in the various organs is easy. The experimented animals were killed at various stages of the disease, and the blood and organs examined in the fresh state. In the case of the latter the tissue was triturated in physiological solution.

The results are given in a table, and the author concludes: That the parasite multiplies first at the seat of inoculation, the peritoneum—*e.g.*, showing this up to the tenth day after inoculation in this situation. The infection then extends to the blood, and it is at this stage that the parasites are most numerous. Soon the trypanosomes settle themselves in the testicles, orchitis being commonly observed. The lymphatic glands are invaded in their turn, and afterwards the cellular tissue, the skin, in œdematous patches, and the nasal mucous membrane.

In all these organs the parasites multiply progressively with the well-known organic troubles common in the disease, and correspond exactly with its clinical history; but the secretions, such as the semen, conjunctival pus, &c., remain free from parasites.

In the spleen, salivary glands, liver, kidneys, suprarenals, lungs, brain, spinal cord, lachrymal glands, thyroid, thymus, bone-marrow, and ovary examination give uniformly negative results, save on a single occasion in the two first mentioned organs.

In short, in the rabbit, *Tryp. brucei* may be more abundant in certain organs than in the blood, and these organs are precisely those which suffer from functional troubles and coarse lesions.

VARIATIONS IN THE ELEMENTS OF THE BLOOD IN NAGANA.

Goebel, Oswald, and Demoor, Albert, in the following issue of the same periodical, p. 137, confirm Van Durme's work on the rabbit by observations on the guinea-pig, in which death takes place in fourteen to twenty-five days.

The parasites make their appearance in the blood in three to six days, and at first the trypanosomes multiply rapidly, but this is followed by a diminution, succeeded by a second multiplication during the last two or three days before death.

During the remission the parasites are fairly numerous in the lymphatic glands and very abundant in the testicles, while none are to be found in the other organs.

This growth of the parasites is associated with a fall in the number of red corpuscles, which may be reduced to a third of their normal number, though there may be a slight increase for a few days before death.

The onset of the disease is marked by marked hypoleucocytosis, but at the end there may be a return to the normal, or even slight hyper-leucocytosis. The number of polynuclear corpuscles is directly proportional to that of the trypanosomes, while the lymphocytes are inversely proportional. The large mononuclear corpuscles become increasingly numerous to nearly the end of the case, and often contain inclusions, which are probably the remains of trypanosomes. There is no increase of eosinophil leucocytes.

"Boll. R. Acad. Med. de Genova," 1906, p. 15.

THE LESIONS PRODUCED BY TRYPANOSOMA BRUCEI IN THE EXPERIMENTAL INFECTION OF DOGS.

Massaglia, Alda, on "Sundry Observations on Experimental Trypanosomiasis, and on the Biology of the Trypanosomes," *ibid.*, p. 6.

The author continues his last year's study of the lesions caused by *Tryp. evansi* in mice, rats, and guinea-pigs by some researches on the infection of dogs with *Tryp. brucei*, and obtained similar results.

The most gravely affected organs are the kidneys, which show hæmorrhages into the cortical substance, albuminoid and vascular degeneration of the epithelium of the tubuli contorti, and Henle's loops, nuclear chromatolysis, and caryolysis. In short, subacute hæmorrhagic nephritis. The cortex of the suprarenals show indications of functional hyperactivity, the liver of subacute hepatitis with fatty degeneration. The adenoid tissue of the spleen is thickened, the splenic pulp shows abundant hæmorrhages, with infiltration of polynuclear leucocytes, while in the Malpighian bodies there is an increase of lymphocytes and large mononuclear white corpuscles.

Glandular enlargement of the lymphatic glands, with hæmorrhages and infiltration of lymphocytes.

The bone-marrow is deep red to the naked eye, and is in a state of marked hæmatopoietic hyperactivity, and contains all the elements of the blood. Leucocytic counts were made in two of the dogs, as well as in some of the guinea-pigs, rats and mice infected with *Tryp. evansi*.

During the course of the disease there is marked hyperleucocytosis at first of all classes of leucocyte, but later on the polynuclear cells decrease in number, while the lymphocytes become more numerous. Figures given for a dog and a guinea-pig: the lymphocytes formed three-fourths of the total, while the polynuclear cells were reduced to 3 per cent. The red corpuscles are reduced to one-third, but maintained a normal appearance. In the earlier period of an infection the trypanosomes stain easily, but are rather smaller than those of following swarms.

Transferred to cerebrospinal fluid or to dropsical or amniotic fluid, the trypanosomes live for a short time. An intercurrent microbic infection (*e.g.*, by streptococci) causes the trypanosomes to disappear from the blood. At the point of death the infected animals were lithæmic.

"C. R. Acad. Sciences," T. cxlii., p. 1229.

EXPERIMENTAL INFECTION WITH TRYPANOSOMA BRUCEI. DESTRUCTION OF THE PARASITES IN THE SPLEEN.

Rodet, A., and Vallet, G., draw attention to the enormous destruction of trypanosomes in the spleen of dogs and rats infected with *nagana*, and carefully describe the various stages of the parasites met with in the spleen pulp.

They consider that the breaking up of the trypanosomes is an extracellular process, whereas it may be remembered that Sauerbech, who studied this question by sectionising the affected tissues, shows that the destructive process takes place in the interior of the macrophages. The spleen juice of healthy dogs has a certain amount of destructive power over these parasites, and the same is true of the lymphatic glands, lymphoid tissue of the intestine, and the circulating blood.

M. Mesnil, commenting on his abstract in the *Bulletin de l'Institut Pasteur*, believes that the present authors have fallen into error, owing to their employing the defective method of smearing, instead of that of sectionising.

"C. R. Acad. Sciences," T. cxliii., p. 135.

THE TEMPORARY DISAPPEARANCE OF NAGANA TRYPANOSOMES IN INFECTED DOGS.

Roux, Gabriel, and Lacomme, Leon. Starting with Rodet and Vallet's demonstration of the destructive effects of the spleen on trypanosomes, the authors tried treating infected dogs with inoculations of ox spleen extract (spleen ground up, by means of Latapie's apparatus, with three times its bulk of physiological solution) in doses of 20 cc.

Three dogs were experimented upon. In two injected subcutaneously phagædenic staphylococcus abscess resulted, while the third, treated by intravenous injection, showed no local ill-effects.

In all three, however, the trypanosomes disappeared from the blood, but followed by relapse in the first dog after seven days, while the others had not been followed long enough at the date of publication.

While admitting the possibility of the disappearance of the trypanosomes may be connected with the supervention of the abscess, the authors prefer to believe it to be the direct result of the spleen extract. The entire publication, however, seems to be premature.

THE SIGNIFICANCE OF EXANTHEMATA IN TRYPANOSOME FEVER.

Nattan-Larrier, L., and Tanon. An European patient, from the Upper Congo, exhibited a vesiculo-papular rash on the arms and thorax, and a circinate erythema on the shoulder, hypochondria on the epigastrum, axillæ, and lumbar region, appearing in simultaneous crops and running their course in ten to fifteen days.

Smears of the fluid obtained by scarifying the patches of erythema showed numbers of trypanosomes, while none could be found in blood from the finger. Erythematous patches of the sort are, therefore, of importance in the diagnosis of such cases.

"C. R. Acad. Sciences," T. cxlii., p. 1482.

THE IDENTIFICATION OF THE PATHOGENIC TRYPANOSOMES. ATTEMPTS AT SERUM DIAGNOSIS.

Laveran and Mesnil. The material employed was the serum of three goats, the first of which had been cured of Zululand *nagana*; the second, first of *nagana*, and then of Indian *surra*; and the third, first of Mauritius *surra*, and then of the *nha-trang* of Annam.

In like case, the mixture of virus which will cure a goat with a variable quantity of the serum of that goat ($\frac{1}{10}$ to $\frac{1}{2}$ cc.) is harmless to mice. The authors have tried to ascertain how these serums react on other forms of virus, so as, if possible, to base on this a method of serum diagnosis for the different trypanosomiases.

With some reserves, they conclude: (1) That the trypanosomiasis of Annam differs from that of India. (2) That the strong virus of the *Togo* of Marlini, which was unaffected by the serums of either of the three goats, is neither *nagana* nor *surra*. (3) That the virus of Schilling's *Togo* is not identical with nagana.

It may be noted that these serums were much less active when injected twenty-four hours previously, or at different parts of the body, though simultaneously, than if injected mixed with the virus.

THE RELATIONSHIP OF ANKYLOSTOMIASIS TO BERI-BERI.

Noc, F. The author found *Uncinaria americana* (Stiles) in 74 out of 77 cases of beri-beri, and in 17 out of 82 Annamites residing in contaminated localities, but never in any one of 31 Europeans suffering from various intestinal complaints. He believes that ankylostomiasis is an important factor in the etiology of beri-beri, and asserts that the administration of thymol effects a surprising improvement in such cases. Our readers may no doubt remember that the anæmia of coolies in the Assamese tea gardens was for a long period known as "beri-beri," until the disease was shown by Giles to be really ankylostomiasis. Have these cases of M. Noc any connection whatever with true beri-beri?

"Archives de Hyg. et Pathol. Exot.," T. i., 1905.

HUMAN TRYPANOSOMIASIS.

Kophe, Ayres. The author has met with fifty-two cases of sleeping sickness from the various East African Portuguese colonies, and has found *Tryp. gambiense* in all of them. For diagnosis he prefers to puncture a lymphatic gland.

In every one of forty lumbar punctures the parasites were found in the cerebro-spinal fluid, even when no nervous symptoms were present, and the characteristic leucocytic perivascular infiltrations of the nerve centres were found in all of the thirty-six *post-mortem* examinations made by him. *Glossinæ* (*palpalis*, *longipalpis*, *wellmani*) were found in most localities where the disease exists. In only one out of thirty-four cases did the cerebro-spinal fluid yield any organisms when incubated on a variety of media. In this instance a diplostreptococcus was found, but M. Kophe nevertheless found this organism in half his autopsies.

No animal experimented on showed the characteristic perivascular lesions, though dog-faced apes and other monkeys were tried, and no better success attended inoculations of the diplostreptococcus, whether the animals were already infected with trypanosomiasis or not. Twelve patients were treated; arseniate of soda, in combination with trypanroth, was tried on two, but was found useless, and afterwards atoxyl was used exclusively, 10 to 15 cc. of a 10 per cent.

solution, every eight to ten days, being well borne. Under this treatment there was obvious improvement, the trypanosomes disappearing from the blood and lymphatic glands, though they persisted in the cerebro-spinal fluid.

The author explains this by the impermeability of the meninges, instancing the fact that he failed to find any iodide of potassium in the cerebro-spinal fluid of patients who were taking that drug. Sooner or later, however, all his cases succumbed. In one case atoxyl was injected into the arachnoid, but the case was already moribund. An inoculation of 10 per cent. lysol was well borne, and no trypanosomes were found after in the fluid drawn by lumbar puncture.

"Arch. Inst. Bacteriol., Camora Pestana," T. i., p. 171.

EXPERIMENTAL TREATMENT OF TRYPANOSOMIASIS.

Magalhœs, A. de. The author tried arsenious acid, followed after forty-eight hours by trypanroth, on a number of infected rats, but with little or no success.

"Ann. Soc. de Méd. de Gaud," T. xxxvi., p. 52.

TRIALS OF RADIOTHERAPY IN EXPERIMENTAL TRYPANOSOMIASIS.

Nobelle, De, and Goebel. Their results were absolutely negative. (The Röntgen rays were employed.)

"Deutsch. Arch. f. Klin. Medecin," T. lxxxvii., p. 98.

THE TREATMENT OF PROTOZOAL DISEASES BY CONCENTRATED LIGHT.

Busck, G., and Tappheimer, V. It is well known that a variety of colouring matters so modify the action of light as to enable it to rapidly destroy living cells, and it was hoped, by first injecting such a colouring agent and then using concentrated light, that blood protozoa, such as trypanosomes, might be destroyed. With the exception, however, of eosine and erythrosine, all the dyes used were so rapidly decomposed in the blood as to be useless, and though trypanosomes and paramœcia immersed in serum so coloured were rapidly killed *in vitro*, the results of the authors' experiments on living animals were not sufficiently encouraging to lead them to hope much from this form of treatment.

"Preliminary Report of the Commission on Anæmia in Porto Rico."

Between March and November, 1905, 18,865 cases of ankylostomiasis were observed, the great majority of which were whites or mullatoes; but though the negroes were less frequently attacked than the whites, and appeared to suffer less in proportion to the degree of infection, many serious cases were to be met with among them. The annual death-rate from the disease is from 5,000 to 7,000.

The belief is expressed that in 99 per cent. of those harbouring the parasite (*Uncinaria americana*, Stiles) the infection has been contracted by the skin. Ground-itch (*magamorra*) is the first symptom of infection, and ankylostomiasis follows. Ninety-six per cent. of the cases of anæmia, in fact, stated that they had suffered from ground-itch, whilst among the healthy who had so suffered half had had the skin disease so long ago that the intestinal parasites might have been voided. The disease is specially rife in the coffee plantations, the work on which is mainly done during the rains. The Commission recommend treatment with thymol, five doses of which is sufficient to effect a cure, and their results are already remarkably encouraging.

"Le Caducée," September 15, 1905.

TEMPORARY DISAPPEARANCE OF TRYPANOSOMES IN DOGS INFECTED WITH NAGANA.

Roux, G. and Lacomme, L. In a paper read at a meeting of the "Académie" on May 28th, 1906, Rodet and Vallet described a series of experiments which showed that, in animals infected with nagana, the spleen is an active centre of destruction of trypanosomes; furthermore, *in vitro*, the spleen appeared to have a *trypanolytic action*. This suggested to Roux and Lacomme the following experiments, which were made with an emulsion of bullock's spleen:—

Three dogs were inoculated with *Trypanosoma brucei*; in from six to eight days trypanosomes were freely present in the circulation. The following day they were given 20 cc. of spleen emulsion; in from two to three days afterwards trypanosomes could no longer be detected, but in one of the dogs, in which a phagædenic abscess developed, they reappeared after an interval of five days.

This phenomenon of the temporary disappearance of trypanosomes in the blood of dogs infected with nagana, after the latter had received an injection of spleen emulsion, is an entirely new one, but one consistent with the prior observations of Rodet and Vallet, who had demonstrated the trypanolytic action of the spleen. This suggests the possibility of being able, by repeated subjections of spleen emulsion, to cause a final disappearance of trypanosomes from the blood of infected dogs.

The spleen emulsion is thus prepared: Take a fresh bullock spleen immediately after the death of the animal, if possible; triturate it in a Latapie crusher, dilute the product in a sterilised salt solution (7 in 1,000) in the following proportions: salt solution 3 parts, spleen 1 part; centrifugalise the emulsion, and inject the supernatant fluid either under the skin, or, preferably, into the saphena vein.—J. E. N.

"Bull. et Mém. Soc. Centr. Vétér.," T. lxxxiii., p. 363.

Lignières, L., records an instance of the infection of a dog with *nagana* in a fight with an infected coati.

"Journ. de Med. et de Chir. Prat."

TREATMENT OF MOSQUITO BITES.

Joly suggests the following mixture for allaying the irritation of mosquito bites:—

℞	Liq. formaldehyd (40 per cent.) ...	ʒiv.
	Xylol	ʒiss.
	Acetoni	ʒi.
	Balsam canaden.	gr. xv.
	Ol. citronellæ	q.s.

Before applying, shake the mixture, and touch the bitten part with end of the wetted cork or small piece of cotton-wool, and then allow the fluid to dry on the skin.

"The Liverpool Medico-Chirurgical Journal," No. 50, July, 1906.

TROPICAL ABSCESS OF THE LIVER.

Newbolt, G. P., reports eight cases of liver abscess which he had operated upon. Four were single abscesses, and all recovered; four were multiple abscesses, and all died. The operation favoured by Newbolt is incision and free opening up of the abscess cavity, but he states that in a deep abscess, with a good deal of liver substance intervening, a special trocar and cannula is possibly of benefit in order to avoid hæmorrhage. In places in the Tropics also, where surgical assistance is unobtainable and the operation has to be conducted single-handed, the simpler operation by the trocar and cannula is commendable. Of the many points raised by Mr. Newbolt, the following are the more important: (1) In all the cases seen by him a history of dysentery has been obtained. (2) Acute hepatitis, leading to abscess of the liver, is due to micro-organisms entering the liver from the intestine by way of the lymphatics, blood-vessels, or biliary channels. (3) An hepatic abscess may present acute signs and symptoms at first, passing on to a more or less chronic form, in which the patient may get about, the presence of pus being completely or for the most part masked. (4) Of the many complications and sequelæ, a suppurating hydatid cyst, an empyema, primary malignant disease of the liver with fever, syphilitic gummata, are the more prevalent, and difficult of diagnosis. (5) The differential diagnosis between

the rupture of a liver abscess through the diaphragm, causing empyema, and perforation of a duodenal or pyloric ulcer attended by the formation of a sub-diaphragmatic abscess, and similarly, after perforating the diaphragm, causes empyema, is discussed by Mr. Newbolt, but nothing conclusive is established. (6) Tenderness over the appendix may or may not indicate that a collection of pus anywhere in right loin or right hypochondrium had its origin in the appendix itself. In some cases the pain in appendix was secondary to pus developed higher up the right flank, in others the pus from appendicitis invades the hepatic region. (7) The presence of *Amœbæ dysenteriæ* in hepatic pus may or may not be an etiological factor in the disease. (8) Stitching the liver to the abdominal wall is, as a rule, impossible; when the liver is exposed, the area around should be packed with gauze, and the abscess remain unopened until four days subsequently.

"Journal of Economic Biology," 1906, vol. I., part ii.

THE EFFECTS OF METAZOAN PARASITES ON THEIR HOSTS.

Shipley, A. E., and Fearensides, E. G., of Cambridge, have studied the effect metazoan parasites exercise on their host from four standpoints: (1) By the mere presence of the parasite in some organ in which it takes up a certain amount of space and displaces a certain amount of tissue. (2) By the migration of parasitic organisms from one part of the body to another. (3) By the loss to the host, which has to feed the parasite, either on the half-digested contents of its alimentary canal or on its more elaborated fluids. (4) By the presence of certain toxins said to be given off by the body of the parasite, either as excretions or otherwise.

They found that metazoan parasites give off toxins which profoundly affect the tissues of their hosts. The fact of an association of a marked eosinophilia with the presence of parasites in the body seem to be a conclusive proof that toxins are given off in considerable quantities by all the better known human metazoa.

"Medical Record," August 18, 1906.

TREATMENT OF CHOLERA BY HYDROCHLORIC ACID.

Palier, E., suggests as a prophylactic against cholera liberal doses of hydrochloric acid with the addition of perhaps pepsin. For the treatment of the disease he recommends washing out the stomach with a 2 per 1,000 of hydrochloric acid in boiled water, and rectal irrigation by 1 per 1,000 of the same acid.

"American Journal of Medical Sciences," August, 1906.

A NEW INTESTINAL PARASITE OF MAN: PARAMŒBA EILHARDIA HOMINIS.

Craig, C. F., of the United States Army, found in the fæces of six natives of the Philippines a parasite not hitherto described. Watery stools with occasionally small amounts of mucus and blood constitute the prominent signs. *Entamœbæ dysenteriæ* were present in all the cases, and *Trichomonas intestinalis* in one case. The parasite appears to pass through an amœbic and a flagellate stage of development.

"Philippines Bureau of Health Report," September, 1904, to September, 1905.

X-RAY TREATMENT OF LEPROSY IN THE PHILIPPINES.

Wilkinson, H. B., states that of 13 cases of leprosy treated by X-rays, 3 have been cured, 7 improved, and 3 not improved. Dr. Wilkinson's theory as to the reason for cure by X-ray treatment is that the leprous bacilli are killed by exposure to the rays, and that their dead bodies are absorbed into the system, and render the persons thereby immune against the living organisms, just as injection of dead bacilli lead to immunisation in plague.

In support of this theory Wilkinson cites the following facts:—

(1) The treatment of one leprous spot on a patient produces improvement in spots at a distance from the one actually treated.

(2) The cure in the distant spots seems to progress parallel to, and to be just as complete as in the one treated.

(3) The best results seem to be obtained only when treatment is pushed to the point of killing or beginning to kill the tissues, which would also probably be to the point of killing the organisms.

(4) Cases in which there are massive localised leprous deposits are most rapidly improved. As in these cases we have an abundant culture on which to operate, and thereby produce immunity more rapidly.

(5) In diffuse general involvement of slight degree or atrophic character where there are only a few scattered organisms we have had little success.

(6) In two well-advanced cases, where the amount of new leprotic tissue was excessively great, the improvement was marked and rapid, but followed by loss of general health and rapid physical decline. This may be an over-dosage, so to speak.

"Journal Royal Army Medical Corps," August, 1906.

MALARIAL FEVER CONTRACTED IN PORTSMOUTH, ENGLAND.

Copeland, Major R. T., and Smith, Major F., D.S.O., report a case of malarial fever in a soldier belonging to the Royal Garrison Artillery, who developed typical tertian ague, whose blood showed abundance of tertian parasites, and in whom the spleen was enlarged. The fever disappeared when quinine was given. The soldier had never been out of England, and the question of infection was diligently enquired into. In the first place, no mosquitoes were found in the barracks (Clarence) in which the soldier was quartered, nor were there any breeding places for mosquitoes near by. A source of infection may have been a fellow soldier, home from abroad, suffering from tertian fever, who was quartered in the same room. The soldier's father lived at Carisbrooke, in the Isle of Wight; he had been in India twenty-four years ago, but according to his statement, he never had fever. Eight days after visiting his father the soldier developed malarial fever; it is unlikely—not to say impossible—that the father could have given the infection to his son; infection was probably conveyed from the comrade in the same room in barracks. By what means the infection was conveyed is a question. Majors Copeland and Smith state that infection by a mosquito was impossible, as no mosquitoes were in the neighbourhood, and suggest carriage by flea or bug.

The case is interesting, but the solution of the mode of infection is, unfortunately, not accurately determinable.

THE PRINCIPLES OF DIET IN TROPICAL CAMPAIGNS.

By Andrew Duncan, M.D., B.S.(Lond.), M.R.C.P., F.R.C.S.
Fellow of King's College; Lieut.-Colonel I.M.S. (retired).

The subject of the food to be supplied to our men in tropical campaigns has to be considered under many heads, amongst which may be mentioned the amount to be given, its variation, its qualification by a hot climate, and the causation of disease by food.

Relation of the Elements of Food to Work and Heat.—Formerly Liebig's theory held good, namely, that the albuminates of the food supplied the force, whilst the non-nitrogenous elements simply served for the production of heat. Lyon Playfair also stated that the transformation of the nitrogenous food in the body was sufficient to account for all the mechanical force without holding that the fats and starches had any share in it. But subsequently physiologists showed that the amount of nitrogen excreted during rest is nearly the same as that excreted during work. The view now generally held is that stated by Fick and Wislicenus, who compare a bundle of muscular fibre to a machine consisting of albuminous material, just as a steam engine is made of metal. Coal is burnt in the latter to produce force, carbonaceous matter is consumed in the muscular machine for a like purpose. Again, as the iron of the engine is worn away and oxidised, so is the muscle also worn away. Much more coal would be burnt in the steam engine with heavy than with trifling work; all forms of energy of the body are derived from the non-nitrogenous elements, hence, during increased work, an increase in the non-nitrogenous elements is required; but as there is also, as in the case of the steam engine, some wear and tear of the body, so it is requisite to supply an increase of nitrogenous material during this increased work.

Amount of Food in Campaigns.—The amount of food consumed must be estimated with regard to the amount of work the soldier has to perform. A fair day's work for an average man is held to equal about 300 foot tons per diem, a hard day's work about 550 foot tons. A march of 10 miles, in heavy marching order, equals 250 foot tons. But on service the soldier has much more work than his mere march; he has his fatigue duties in camp; there are, in fact, numerous additional occasions for more bodily and mental waste, and very likely the quality of the food supplied is not so good as in peace. Hence, De Chaumont laid down that a war diet should provide for a minimum of 350 to 400 foot tons, and be capable of being increased at the shortest notice to 500 foot tons. Such an amount would be furnished by a diet supplying—

Nitrogen	...	350 grains.
Carbon ...	...	5,500 ,,
Salts ...	...	450 ,,

whilst the increased number of foot tons would require—

Nitrogen	...	450 grains.
Carbon ...	...	6,500 ,,
Salts ...	...	500 ,,

Climatic Qualifications.—The income of food in the body results in an outcome of bodily movement and of heat, $\frac{1}{5}$ to $\frac{1}{6}$ being expended as mechanical force, and $\frac{4}{5}$ to $\frac{5}{6}$ as heat. With the increase of external heat Kering and Funke have shown that less production of body heat takes place. Hence, inasmuch as less heat is required to be produced in a hot climate, it would appear that less heat-producing material is required. Dr. Carpenter has shown that in very active work in hot climates the necessary temperature of the body is maintained by such active work. Again, in campaigns the first affections to appear in the men are those of the digestive system, whilst it is well known that in the East the more nearly the diet of the European is assimilated to that of the native, in the substitution of fruits and farinaceous substances for oleaginous articles, the less will be the liability to disordered digestion. Professor Maclean, of Netley, in this respect, used to warn his class never to eat meat more than once a day. Dr. Crawford held that in the Tropics the meat should be reduced and the vegetable increased. Mr. Stanley, the African explorer, testified against "gratifying the seemingly uncontrollable and ever-famished lust for animal food." Hence, in the Tropics, in peace time at any rate, the food of the soldier should contain a large proportion of fresh vegetable and less animal food. But with the onset of a campaign we have the entrance of the factor of excessive work. Is, then, the *regime* of peace in hot climates to be followed out in war? Speaking personally, a diminished desire for animal food and fat in the hot weather was experienced when *stationary* in any of the camps on the line of communication, but when *marching* no such feeling arose. Hence, it would appear that during *active* operations in a campaign in hot climates an extra meat ration is indicated; this was ordered in Lord Roberts' great Cabul-Candahar march and was fully enjoyed, nor did it lead to any digestive disorders. In the *resting* stage of a tropical campaign let animal food be in part substituted by vegetable, let the fats be diminished, the carbonaceous elements being furnished rather by the starches. In the *marching and fighting* stages, on the contrary, let the animal food resume its wonted proportion.

The above general principles should be conjoined with the following considerations: First, at the commencement of a campaign the ration must be *ample*. In the Egyptian operations of war in 1882 the men had to be fed for the first four days on preserved rations, a proceeding fraught with danger. Secondly, the food should be *varied*. Digestion is never so likely to be upset as when there is a monotonous diet. A good example of this was afforded during the first four weeks of the Abyssinian War, where the food was restricted to beef and flour with no vegetables. Bowel complaints immediately begin to be rife. The necessary variation may be obtained by the issue of the different tinned meats from Australia and New Zealand, but the greatest caution must be exercised in this particular. No tin should ever be passed which is blown out. As regards vegetables, compressed should never be used; they are tasteless and stringy and set up diarrhœa by their irritating mechanical properties; they have lost their albumen

and salts, and consist chiefly only of the cellulose frame work. They were universally condemned in the Chitral campaign, causing diarrhœa, and were, moreover, scarcely eatable unless soaked for twelve hours. It is also always preferable to drive cattle with the force, rather than to carry meat supplies. Lastly, never give salted and preserved rations at a stretch, or, in fact, never, if possible, let the men undergoing severe exertion have only tinned meat for more than one day.

With regard to the question of *alcohol*, there should be, of course, no daily ration of rum, but total abstinence is to be avoided. There are occasions when a ration of alcohol has proved to be of the greatest value, such as when the men arrive in camp drenched with a tropical shower, tired out, and with no change of clothes. But if possible, light red wines should be issued twice or thrice a week; these are grateful and refreshing in a hot climate, and greatly preservative against bowel complaints and cholera. Mr. Stanley recommended strongly their use. Where renewed exertion is required after a long march, a ration of rum is beneficial, as was shown in many campaigns, *e.g.*, the Ashanti, the Galeaka-Gaika, the Eastern Soudan, &c. Lastly, alcohol, in the shape of a rum ration, is contra-indicated in all cases where bowel complaints, enteric, cholera and other zymotic diseases are likely to occur.

Preserved Foods in War.—Several varieties of these are on the market. In the African War, Kopf's Consolidated Soups were used and answered admirably. Whitehead's Variegated Soups were much liked. The most satisfactory of all was "Erbswurst," for it was highly nutritious and most easily prepared. A packet of this portable soup can be issued when it is impracticable to supply a full meat ration; in Lord Roberts' march each soldier had half a tin before starting the day's march. Maconachi's field ration was found to be excellent in Ashanti, in Egypt, in the Soudan, and in the South African Wars.

Scurvy in Tropical Campaigns.—Now that this disease has disappeared from our Mercantile Marine, owing to the ships carrying lime juice with them, scurvy probably is most frequently seen in India, especially on the N.W. frontier. Lime juice should always be part of the ration of war. I well remember being a member of a Committee on a certain regiment in Afghanistan, which had to be sent back on account of the severe outbreak of scurvy attacking it, fully one half of the men showing signs of the affection. In the China War of 1860, in Looshai 1871, in Suakim in 1885, there were outbreaks of scurvy, no lime juice being in the ration, whereas where this was given, as in the New Zealand War of 1863-65, in Ashanti in 1873, in Duffla, 1874, in Malay and Sunghi-Ujong, 1874-76, in Zulu, 1879, in Egypt, 1882, in Aka, 1883-84, in Dongola, 1886, amongst other campaigns, no scurvy appeared.

In recent wars, jam has been supplied to the soldier, this also, besides its anti-prophylactic value, is of good effect in counteracting the onset of fatigue by reason of the sugar it contains. Vaughan Harley has shown that 3,000 grains of sugar added to a small diet, increased the work done in the proportion of 6 to 39 per cent., whilst 3,700 grains added to a full meal, with eight hours a day labour, increased the work accomplished by 22 to 36 per cent. Should lime juice not be present with the force, what other means have we? My friend, Surgeon-Major G. Griffith, when P.M.O. of the Suakim Field Force, stopped an outbreak by recommending the men to eat their rations from the animal directly it was killed. The late Professor Parkes also recommended that in lieu of common salt, bitartrate of potassium should be taken at meals. This was given with marked benefit to the 21st P. I., during their return from Abyssinia, when scurvy attacked them on board the transport. Lastly, on the occurrence of four cases of scurvy in the Mountain Battery to which I was attached in Affghanistan, I recommended a daily ration of vinegar, as we had no lime juice, and no further cases came into hospital.

In conclusion, to illustrate some of the above remarks, I now give the scale of diet allowed to us in Afghanistan :—

Fresh meat (exclusive of bone)	1 lb.
Bread	1¼ lb.
Biscuit	1 lb.
Rice or flour	4 oz.
Sugar	3 oz.
Tea	¾ oz.
Salt	⅔ oz.
Green vegetables when procurable	6 oz.
Potatoes	12 oz.
Dhall	1 oz.
Rum	1 dram.
Tobacco	½-¾ lb. per month.

During the march to Candahar the meat ration was increased to 1½ lb. and 1 tin Kopf given daily.

The diet gave roughly :—

Nitrogen	428 grains.
Carbon	5,298 ,,
Salt	346 ,,

The chief remark to be made concerning the diet is that the amount of carbon was too small and this was also shown in the increased diet for the Cabul Candahar march, for the only factor that distressed the men and officers was *fatigue*, the amount of carbon being 5,702 grains instead of 6,500 grains. To ensure a proper amount of carbon in the diet, cheese, in which the proportion of N. to C. is 1 : 7 should be added to the diet. Bacon is also an excellent article of diet to work on, the proportion of N. to C. being as 1 in 24, or porridge, the proportion being as 1 in 21.

FOOD OF THE NATIVES OF INDIA.

By Major G. H. Fink, I.M.S. (Retd.), M.R.C.S.(Eng.), L.S.A.(Lond.).

The subject of food of the natives of India, though a very wide one, is of interest from a physiological, chemical and economic point of view. It is almost imperative that medical men should study the food, its constituents, and the elementary or proximate principles in India if practising either in the great cities, or the Mofussil, as the country districts are termed.

We are told that "the enumeration and classification of the food or aliments necessary to maintain human life in its most perfect state have been usually based

in the deduction of Prout, that milk contains all the necessary aliments and in the best form."

Wherever you go in India, you will find that there is great value set on milk and its products; also on sweetmeats and sugar, by the Hindu population, from the upper classes down to the labourer. The cow is worshipped by the Hindu as sacred, because of both food and drink which it provides for human life. The Hindus boil their milk for a considerable time before drinking it, and they sweeten it very largely with quantities of either white or brown sugar, according to the taste.

There are three principal products derived from milk which the Hindus use, viz:—(*a*) Dhyé (sour milk after lactic acid fermentation has set in) which they take with sugar; and the poorer classes take it with the rice left over from the previous night's meal, and sweeten it with sugar. This is the first meal very often before going to their work, which is their breakfast. (*b*) Malié or cream, which is also eaten with sugar, or made into sweetmeats, which the middle classes—who are unable to return to the midday meal owing to business or duties in Government offices—consume as their lunch or *tiffin*, together with other sweatmeats. (*c*) Chhanah, or a firmly set curds resembling cream cheese, which is also made into square cakes soaked in syrup, and used as sweetmeats. (*d*) Clarified butter or *ghee*, which is used for cooking and frying all kinds of food. I need hardly discuss the value of each of these articles, which are well known to medical men, now that I have described them. In considering the diet of the natives of India one has to divide the diet of the Hindus and of the Mahomedans respectively; then subdivide each of these according to their *status* and wealth; and last of all consider the various castes, and caste prejudices of the former, since meat or flesh is allowed in the case of some, but withheld from others, owing to caste.

It is erroneous to suppose that the whole of the natives of India are vegetarians, in the strictest sense of the term. This idea seems to have gained acceptance from the fact, that the wants of the natives, chiefly the Hindu population, are few and simple, and that they confine themselves to the actual necessities of life in the matter of food. Also, because rice, pulse, flour for bread, vegetables and fruit are largely consumed. Rice and flour are the staple articles in use as food, because rice grows plentifully in some parts of India, and flour in others, and according to the one or the other being plentiful, so the people, whether Hindus or Mahomedans, use it, because it is cheap and meets their requirements and their purse. Pulse or dhâl is most generally used throughout India. It is a form of lentils, and is most nourishing, sustaining and fattening. There are several kinds—*moong, musoor, arhar and chânâ*. *Moong* is considered the best but is more expensive than the others. It is a most appetising diet when made properly, and is usually served up with boiled rice or chappaties (flour cakes of unleavened bread). The labouring classes throughout India have this as a daily food with either rice or chappaties, according to the district or province growing rice or wheat plentifully. In Bengal proper, and Assam, rice is consumed more largely, while in Upper India, flour. Among the better and the wealthier classes in Bengal and Assam, in addition to the above articles mentioned (rice and dhâl), fish, of various kinds, which is easily digested and contains a deal of phosphorous, is cooked as a curry in oil (the expressed mustard oil), and there is generally a vegetable curry also served up at the midday or the evening meal. Hilsah and Bekty fish are the best kinds used, and the former contains a deal of fatty matter, and in value is equivalent to mackerel, if not higher in its proportion of nitrogen. Some cheaper forms of fish are used by the rich as well as the poor, fish being very plentiful, as a rule. Mutton is also permitted to be eaten by Hindus, but in Bengal and Assam fish is preferred, owing to its properties being valuable for brain workers, and, being easily digested, is a suitable form of diet for those who lead a sedentary life.

Among the Mahomedan population, wherever you see them, they consume more flesh than the Hindus, and are permitted to eat either fish, fowl, mutton or beef. Even the poorer class of Mahomedans eat more animal food than the Hindus, but in some parts of India, Hindus are quite as strong on animal food (mutton and fish) as Mahomedans. The strictest vegetarians are the *Jains*, a sect of which a great many of the mercantile caste of Upper India are members. They abhor the taking of life in any form, and many of the strictest among them will eat their last meal before candle light, because the flame attracts insects and destroys them. "Jainism," we are told, "is one of the most important of the living cults among Hindus. It is professed by at least a million men, and some of these are among the wealthiest and most refined in the Hindu community."

Leaving Bengal and Upper India, we have to consider Bombay, Madras and the Central provinces. As to the consumption of rice and flour, respectively, by the inhabitants of these provinces, they follow much the same rule in the matter of *status* and *caste* as in Bengal and Upper India in the choice of their staple food, and the various additional articles of flesh, fish, vegetables and fruit, as well as pulse.

Ghi, or clarified butter, is an article of diet which both Hindus and Mahomedans of all classes believe strongly in as possessing valuable nutritive properties, and cannot be dispensed with in cooking their food as well as their sweetmeats of certain kinds, which need frying lightly or smearing over the surface with, to give it a flavour. The poorer classes in Bengal and Assam who cannot afford *ghi* (which is about one rupee the *sir* = 2 pounds), use *expressed mustard oil*, which is also valuable and goes a longer way than ghi. Expressed mustard oil is always used for cooking fish in, and as an inunction among the Hindus, who smear their children's bodies with it from the day of their birth, and later on in life use it over their hair, since it is supposed to have the excellent property of keeping away colds and catarrh, and this has been greatly proved by experienced and mature doctors in the country to be the fact.

I think, with regard to Madras, Bombay and the Central Provinces in the matter of food, Madras, which is adjacent to Bengal, in a large measure is similar in the consumption of the various articles of food in use among Hindus and Mahomedans respect-

ively. The Madrasis, of whom a large number are Roman Catholics, live very similarly to the way their masters live in the matter of food. Bombay holds a mid position between Bengal and Upper India; while the Central Provinces follow much the same line of diet as the United Provinces of Agra and Oudh, which is practically Upper India, including the Punjaub.

I have left the question of drink, and that of air, out of this paper on the food of the natives of India, although I must say that great stress is laid by the natives of many parts of India on the various kinds and qualities of water for drinking and cooking purposes, since some are supposed to aid digestion as well as easy cooking of their rice and pulse, while others retard digestion and cooking.

If we analyse the various kinds of food in use in India by the rich as well as the poor, we cannot help coming to the conclusion that, on the whole, the food is fairly well balanced in the matter of the elementary principles of the diet of both Hindus and Mahomedans. The Hindus, though largely vegetarians, live on food rich in carbo-hydrates and hydro-carbons; but they are, at the same time, large consumers of milk and those products of milk which are healthful and nourishing. In Bengal and Assam, fish supplies largely the nitrogenous element; while in other parts of India, fish and mutton are used. The Mahomedans, who form about the fifth of the total population of India, live on very similar food to the Hindus; eat less sweetmeats; but more animal food (mutton, beef and goat's flesh). Their food, on the whole, contains a larger proportion of the nitrogenous principle than that of the Hindus. The poorer classes of both Hindus and Mahomedans (except the hunting class and the wandering tribes, as well as the sweepers, who are the lowest menials in our household and eat the leavings of our food), as a whole, though contented and happy with their rice and flour with lentils, have some cause for complaint in the matter of luxuries which they can barely indulge in. In seasons of rich harvests or poor harvests, their lot remains the same, and they are not one bit better off nor worse off. It is only in times of famine and great scarcity of food that they have to fight hard against disease and death, and then their lot is a deplorably unhappy one, until relief comes through the Government. There is not the least doubt that within the last twenty-five to thirty, or more years, the price of food has risen, and the rate of wages accordingly of domestic servants, which naturally hits the better classes under Government pretty hard. Moreover, milk and ghi, which the Hindu population attach such great importance to as articles of food, have risen in price, owing to the supply not being up to the demand; but these are questions which are outside the trend of this paper, and therefore cannot be considered here.

In taking the question of the food of the natives of India into full consideration, there is not the least doubt, that, on the whole, it is the most suitable to the climate and their wants, and is a diet which is economical as well as scientific, because the nitrogenous and non-nitrogenous principles, and the mineral salts and vegetable acids, are in that proportion which suits their constitution. In Bengal proper, the carbo-hydrates and hydro-carbons consumed, are, I should say, somewhat in excess of the standard of health, among the better classes.

I have left the Parsi population of Bombay out of this paper, since their standard of living is more Western or European.

FOOD AND DIGESTION IN WARM CLIMATES.

By James Cantlie, M.B., F.R.C.S.

The Food of Natives of the Tropics.

We are usually told, and home-dwelling British folk believe, that the natives of the Tropics live on rice. During the Russo-Japanese War the newspapers, referring to the extraordinary exertions of the Japanese, stated, in reference to their diet, that all the hardships of the campaign were undergone by troops whose sustenance consisted of a handful of rice mixed with water. This misleading statement is in harmony with the rooted belief that the natives of the Tropics and sub-Tropics live on rice.

For China, the country best known to the writer, the same statement is believed to hold good. What are the facts? Every Chinese contractor engaged in any large undertaking knows that he can only get good work out of his men if he feeds them well. Their early morning meal consists of soft-boiled rice "conjee," but that is only the chota-hazra of the Indian. The forenoon meal, or breakfast, consists of fish, or fat pork, vegetables, rice and tea. The midday meal may be again soft-boiled rice, but the afternoon or evening meal consists also of fish, pork, vegetables, rice and tea. The rice is in no larger proportion to the meal, perhaps not quite so large, than is bread in the European breakfast. To say that the Chinaman lives on rice is, perhaps, not so near the truth as were we to state that the European lives on bread.

In almost every nation of the Eurasian continents, except in Britain, two main meals during the day, partaken in the forenoon and late afternoon, is the rule, so that the hours of diet and the kind of food is in China what is customary elsewhere. It is impossible to work, or even live on rice alone; it is impossible for soldiers, or for labourers, to continue for more than a day or two on rice alone and remain fit for duty. In British campaigns we know soldiers go for a day or two on a few hard biscuits, but three days of a biscuit diet, or even a bread diet, ends in collapse from semi-starvation. It is as true that British soldiers went through the South African Campaign on biscuits as it is to say the Japanese fought their arduous battles on rice. Yet does this insane belief, that the natives of tropical and of sub-tropical countries subsist on rice prevail, and the elimination of such nonsense seems impossible.

A Vegetable Diet.

Vegetarianism is a potent cult amongst a certain section of British town dwellers at present. It is regarded as if it were something new and advanced, and amongst what, for want of a better name, may be termed "cranks," vegetarianism is preached as if it were a new Gospel. "New" or "advanced" persons, be they men or women, amongst other fads affect

vegetarianism and regard an all vegetable diet as entitling them to be classed, with those types of degeneracy known, as "advanced" people. A so-called vegetable diet has been, and, it is hoped, will continue to be, the food of many stalwart people; it is nothing new; it is an all-sufficient and time-honoured means of sustenance, and is not the creation of modern minds. The belief that vegetarianism is a new cult is as true as that the natives of India and China live on rice; ignorance is the explanation of both beliefs, but the eradication of ignorance of this stamp appears an impossible task. The term vegetable diet is a misnomer for the most part, for it includes, as a rule, milk, eggs, and not infrequently butter and animal fats, in the form of dripping, &c., used in cooking. That one can subsist, thrive and work hard on this inclusive vegetable diet does not surely want to be told; in many countries we find it used. In the more northerly countries of Europe a diet similar to that consumed in the Eastern and North Eastern counties of Scotland amongst farm servants obtains. Take the diet of a farm servant in Scotland, at any rate, up to quite recently—Breakfast: oatmeal in the form of porridge with oatcakes and milk. Dinner: mashed potatoes or brose, *i.e.*, oatmeal with boiling water or hot milk poured over it and flavoured with vegetables, oatcakes and milk. Supper: cabbage, or kail, or potatoes, with oatcakes and milk. On Sunday: Broth made from beef bones or neck of mutton with vegetables. Beef or mutton was eaten only during a few days in the year—Christmas Day, New Year's Day, and perhaps on one or two other occasions. Theirs was a vegetable diet, and, with the exception of milk, an all vegetable diet. Yet did these men thrive and work hard on this diet, and were as good specimens physically as any in the land. This is, from some standpoints, a more meagre diet than that of the Chinaman, who is foolishly believed to live on rice, and it is more simple and more thoroughly vegetable than professed yclept vegetarians follow, who frequently include not only all the vegetable products of the Orient—sage, rice, tapioca, &c., but also eggs and milk. It is therefore untrue that vegetable eaters are found only in warm countries.

Varieties of Food.

Cow's Milk.—To home-dwelling Europeans it is incredible that milk is not used as an article of diet by people of every nationality. Several races, however, do not use milk in any form. The Chinese, and all other Mongolian peoples, constituting almost one-fourth of the entire population of the universe, do not drink milk, and several other races, especially the Malays of the Archipelago, follow their example. Babies in China, when weaned, are given the water rice is boiled in (Conjee), as we give milk to the children, and they thrive well upon it. In the districts of Scotland mentioned above, milk is (or was until quite recently), taken in larger quantity than by any other adult people in the world. The milk used is not the milk as it comes from the cow, with ten per cent. cream, but almost eight per cent. of the cream is removed by skimming (not separated), and the amount taken during the day would be between 2½ and 4 pints. It is doubtful if milk with the natural amount of cream could be taken in such quantities without making the consumer "liverish"; on the other hand, separated milk (quite different in quality to skimmed milk), would, in all probability, be insufficient to give the nutriment required. No other section of the human race consume milk to this extent, and as the Tropics are approached, cow's milk is less and less used. Goat's milk is substituted in some parts; ass's and mare's milk, either naturally or in a fermented state, is taken, and buffalo's milk is used by some peoples. Buffalo's milk contains a much larger proportion of cream, some seventeen to eighteen per cent., but the skimmed buffalo's milk is poor in food-giving properties compared with cow's.

Europeans in the Tropics, wherever possible, import European or American cows for milking purposes, owing to the native cows, in the far East, at any rate, not yielding the same quantity or quality. Tinned milk, especially Nestlé's, is largely used by Europeans in warm climates. Were it possible to issue Nestlé's milk in smaller tins, there is little fault to find with its use in the Tropics; but owing to the size of the tin sent out by the Company, the contents cannot be consumed in one day, and in a tin once opened the contents rapidly become quite hard in a dry climate, or in a warm, moist climate they are apt to become mouldy. Were it possible to export Nestlé's milk in smaller tins, so that the opened tin need not be kept from day to day, it would be a great gain hygienically; but it is doubtful if it could, under these circumstances, be exported at a sufficient profit without largely increasing the cost to the consumer.

Sterilised milk, *i.e.*, fluid milk sterilised before being put in bottles, as that known as Dahl's, is theoretically excellent, but the cost and the difficulty of transport are rather prohibitive for general and continued use.

On board ship the absence of fresh milk is greatly felt by invalids returning to temperate climates, and sterilised milk is, perhaps, the best substitute under the circumstances.

In England, milk as an article of food has well-nigh disappeared in many country districts. In the neighbourhood of all large towns the farmer is pledged by contract to sell to the milk-agent from the town all he produces. The farm is a "tied-farm" as much as a public-house in the hands of a brewer is a "tied-public-house." The country children have to get along as best they can without milk, and as bringing up children at the breast is going out of fashion amongst even the rural population, the children are under fed, and rickets is more common in country villages round London than in the city itself. The rural population of large parts of England at the present moment have the poorest diet of perhaps any peasantry in the world. Tea, bread, cabbage and occasionally potatoes, is their staple food, yet do the "educated classes" believe that in the Tropics the natives live on rice, whilst the "roast beef of Old England" for adults and milk for young people is the staple diet of all and sundry in the British Isles. Two-thirds of the rural population in England now-a-days taste beef perhaps once a month, and have milk, if at all, only in teaspoonfuls with tea.

This is not the place to expatiate on a people thus

placed; I have dealt with that elsewhere. The physical decline of a people with its rural population insufficiently and inappropriately fed is not far off.

Beef and Mutton.—It many parts of the Tropics fresh beef and mutton are unobtainable. Cattle may not be reared in the district, and imported cattle are usually employed as beasts of burden.

In out-of-the-way parts of the Tropics beef is wholly unobtainable; the population may be too small to consume, or too poor (as in many rural parts of Britain) to buy, sufficient of a freshly killed ox to make it pay to do so; this obtains not only in the Tropics, however, but in rural districts in Britain; so the "travellers' tales" on these points, although they amuse towns' folk in England, are true not only abroad but at home.

In the equatorial and the tropical zones north of the equator the consumption of beef by the natives is almost nil, and in the sub-tropical and northern regions it is seldom used. In southern sub-tropical countries—Australia, the Cape and South America, cattle grow and flourish, and the consumption of fresh meat, by Europeans especially, is as customary as amongst the better off classes in Britain.

Sheep are distributed very irregularly over the world, for in many parts it is impossible for sheep to live. It is not climate so much as food that is the determining factor, for in Southern China and in Japan where there are no sheep, it is the pasturage that is wanting. Fresh mutton and beef, therefore, is difficult to get in many parts, mainly owing to the environment being unsuited to the rearing and feeding of cattle and sheep, and partly from the inability of the people to buy imported meat.

Breeds of Cattle and Sheep.—It must be remembered that cattle are utilised very largely, not only in tropical but in some temperate countries, as beasts of burden. There are milk cows and draught oxen in the country it may be, but these are neither by a breed nor on account of their age when killed of a quality that produces wholesome and nutritious meat. In Britain, cattle are fed and killed at about two years of age, and from these and these only can the best beef be obtained; in most other European countries the breed of cattle is of inferior quality and do not reach a profitable killing age until one or two years later, necessitating thereby longer keep, that is, more expense and a higher charge for beef were they killed. The consequence is the farmer cannot afford to keep oxen for four years earning nothing, so he puts them to the plough and their muscles become so tough that their beef is leathery and affords but little nutriment.

It comes about, therefore, that cattle are either killed (except in Britain) as calves or allowed to reach the advanced age of ten or twelve or more years before being killed.

The reason that veal is used so commonly in France and Germany is attributable to this cause. Farmers cannot afford to allow the animal to attain full growth for market purposes as they have not the breed of cattle, nor have they the pasturage, turnips, &c., necessary to produce the highest class beef. Their animals when allowed to mature are utilised for farm work, and when killed their muscles are so tough that the beef requires all the tricks of the culinary art to render it fit for consumption. Hence the superiority of "continental" cooks compared with British cooks; the former find it necessary to disguise the poor quality of the meat, the latter are not ashamed to produce the beef as it is, culinary tricks being unnecessary.

The quality of mutton depends greatly on the breed of the sheep. In Australia the wool-producing sheep are more sought after than are the flesh-producing sheep grown in Britain. The quality of mutton, obtainable from sheep from which wool is most profitably grown, is quite inferior to the class bred and fed for killing purposes; and as the farmer keeps the wool-producing animal for as many years as possible, it comes about that, not only from the quality point of view, but also from that of the age of the animals when killed is the mutton inferior in nutriment. It is plain therefore, that beef and mutton may be good enough from the inspector's point of view, but may be tough to digest and wanting in nutritious properties. Such flesh appeases hunger, no doubt, but is not calculated to give bulk for bulk the same nutrition as a food. In this way many dietary peculiarities of tropical life may be explained. More meat has to be eaten to get the sustenance necessary when the meat is of inferior quality. This may be the reason for the accusation made against Europeans dwelling in the Tropics that they eat too much. Certain it is that most Europeans eat more meat (when they can get it) in the Tropics than at home. Some say it is because the climate is exhausting and more strengthening food is required; but the real reason, no doubt, is that the nutritive quality of the beef and mutton is inferior, and that more has to be taken to supply the bodily wants, thereby taxing the digestive organs, which in hot climates are usually feeble, and bringing a train of gastric, hepatic and intestinal troubles.

Frozen Meat.—Could frozen mutton be introduced into tropical countries, a great food problem would be solved. In large cities on the coast cold storage would allow of a plentiful supply of mutton, and perhaps beef, being available for residents in the town itself, but in up-country districts the introduction of chilled or frozen meat is, in the present state of our knowledge, impossible. Not that the sheep of Australia or New Zealand affords the highest quality of mutton, for they are chiefly reared for the wool they produce, and the carcass has, up to recent years, been a bye-product. Now, by freezing or chilling, the bye-product has a commercial value, although it never can be, from sheep of that breed, of the highest.

Fowls are generally distributed through the universe, and there are no parts of the world, so far as I know, where fowls cannot be found. The wide distribution of the fowl is an important factor in the spread of civilisation, for it is a question if Europeans could live in many of the out-of-the-way districts they do were it not that they can have eggs or fowls to eat. The nutritive value of chicken is relatively small, however, and is frequently difficult to digest; moreover the monotony of eating fowl day after day, and month after month, let the fowl be cooked in ever so many ways,

palls upon the appetite after a time, and digestion and nutrition suffer.

Curry, so largely used in tropical countries, is not only the staple form of diet of many natives, but is used also freely by the Europeans dwelling in warm countries. Rice is the basis of the dish, and with it is a congeries of materials, which may consist of fish, flesh, or fowl, with vegetable additions of sorts. The sauce (curry really means sauce, from the Tamil word *kari*) is composed of condiments varying in potency; ginger, pepper (white, black, or cayenne), and various spices give flavour and "nip" to the meal. The use of pepper is, of course, an Oriental custom, and the stronger forms of pepper seem requisite as an article of diet. The therapeutic use of pepper seems to be not so much a stomachic tonic as an intestinal stimulant, and chiefly as a stimulant to the large intestine. It is the large intestine that first flags in its duty in the case of the natives of tropical countries. Constipation is one of their chief complaints, and the atonic condition of the colon is the chief cause. Black pepper is a stimulant to the colon and rectum, and its extensive use in warm climates is physiologically justified by what has been proved by therapeutic investigation and the experience of centuries. Constipation is combated by the natives of warm climates by pepper and spices in the food, by castor oil occasionally, and largely by the position assumed during defæcation—the natural or squatting position. Our modern closet with its high seat is a great detriment to defæcation, especially in habitual constipation, and were people thus afflicted to resume the "natural" position a great deal of the suffering due to piles would be prevented. Some people overcome the difficulty by standing on the seat—an awkward and an indelicate proceeding. The use of a high stool for the feet in front of the closet seat will really give a position sufficiently "squatting" to overcome the difficulty. Curry, therefore, if properly made, is an hygienic dish of value; and should not be regarded with the suspicion it is looked upon in Britain, where badly cooked rice, particles of tough, twice-cooked meat left over from a three or four days' old joint, and made hot to blistering strength with curry powder is the rule. The rice and meat should be served in separate dishes and the condiments added by the consumer himself, or herself, at table, and not by the cook. According to the state of one's digestion so may condiments be added, the people with atonic intestines requiring a larger helping.

The Basis of Special Preparations.

It is impossible to deal categorically with each individual article issued by any particular firm. After all, it is the firm—the people who make the articles for consumption—to whom we have to look for protection in this matter. The show preparations of one firm may be as good as another, but the ordinary articles made to sell may be of quite another character. Given a firm that "can afford to be honest," and we have sufficient guarantee that the goods are what they pretend to be. Mistakes may be made, and faulty raw material may occasionally find its way into the manufactory, but in a firm with a good name to maintain, and not to lose, the public can rely that the materials employed are the best that can be obtained. Lately the American canned goods scandals have shaken the confidence of the public in all kinds of preserved foods. What was going on in American canning factories was well known to manufacturers of food products in this country, to all medical men, and to all who cared to listen to what was said and written. The warnings were disregarded, and British manufacturers were eclipsed in the market; now, perhaps, people will patronise the products of their own countrymen, where the materials used can be inspected, and the process of preparation watched. That British producers of foods of this description have taken infinite pains to ensure cleanliness of premises and wholesomeness of materials, is well known, and we look forward to still further improvement in this important department of food supply.

The basis, the "granulated powder," used by several manufacturers in this country is professedly obtained from America. This, perhaps, is commercially imperative, for it is impossible at the present price of beef-teas, essences, jellies, &c., in the market, that prime beef can be used in their manufacture. The "ox in a bottle" theory is all very well in the form of an advertisement to induce the public to buy the goods, but oxen in this couutry are not obtained for a few shillings, nor yet for a few pounds. An "ox in a bottle" would cost at least £25 instead of about as many pence at which it is sold. We would urge on manufacturers not to be afraid of price; beef is an expensive commodity, and its issue in the form of concentrated food will almost double its value, so that it is, and it must ever remain, expensive. The products at present in the market are much too cheap to command the serious attention of medical men, and we can assure the manufacturers that they will gain higher commendations from the medical profession upon their products, when they issue them at a price which even the most embryonic of financiers can appreciate to be necessary if the "basis" of the materials is obtained from the best beef.

Alcohol.—The natives of warm climates, both by their religion and their habits, shun alcohol. It is in no sense a food, and Europeans in the tropical countries would do well to avoid its use altogether.

Spirits and beer in hot, moist climates are positively detrimental to health; light wines, white or red, do least harm. Champagne, taken after excessive fatigue, about sunset, is perhaps the safest form of alcoholic beverage. It should not be taken with meals, but only on reaching home after a fatiguing march, or long exposure to wet.

Tea.—As a stomachic tonic, and as a safe way of introducing fluid to the system, tea would seem beneficient and hygienic. It was evidently introduced by the Chinese, owing to the calamities arising from drinking unboiled water. Deep well water is almost unknown in China, and the shallow wells and streams are so apt to become polluted, owing to the habits of the Chinese, that experience dictated the necessity of boiling the water. But, boiled water being insipid, and the object of its being boiled not being evident to ignorant and thoughtless people, the water was

"flavoured" by the leaves of the tea plant, a custom which has become widespread. It was, no doubt, for hygienic purposes tea was introduced, but the abuse of tea-drinking has brought many evils in its train. The Chinese drink tea after finishing their principal meal, and, in fact, as a drink at any time. They do not drink tea during their meal, but after the meal is finished. The pernicious system of drinking tea during a meal is one peculiar to British folk, and the habit is fraught with many dyspeptic troubles. The best China tea, prepared by pouring boiling water over the leaves and immediately pouring the water off the leaves, is a wholesome fluid, calculated to aid digestion, especially when taken after the meal is finished. Tea taken *with* animal food, be it eggs, fish, flesh or fowl, is a certain means of producing dyspepsia, for when the tea is "drawn" for a long time, and when the tea used is of an inferior quality—the method and material usual in Britain and Australia—the tannic acid of the decoction, uniting with the albumen of the animal tissues, produces a leathery compound which no gastric juice, however potent, can penetrate and digest. Tea used as the Chinese use it is a hygienic drink; as it is usually used in Britain and by British folk throughout the Empire it is detrimental to the public health.

Coffee.—Two or three mouthfuls of good coffee after a meal is an aid to digestion; taken in quantity, breakfast cupfuls, it is an impediment to digestion, and diluted with half milk and taken with a meal of eggs, fish, fowl, or flesh, is still more so.

Tobacco.—In moderation, and smoked soon after a meal, the deleterious effects of tobacco are infinitesimal. When indulged in to excess, say six to eight cigars, or fifteen to twenty cigarettes, or 1 oz. of pipe tobacco a day, especially in a moist, tropical climate, tobacco is an injurious cardiac depressant.

SPECIAL FOOD PREPARATIONS.

Beef Teas and Jellies; Chicken Soups and Jellies; Calves-foot Jelly.—Home-made beef-tea made from prime beef (top of the round) has the advantage that "we know what is in it." That, however, does not prove it to have nourishing properties. In fact, except as a stimulant from the salts it contains, it gives but a meagre nutriment to the system. Home-made beef essence is usually given in so concentrated a form that it frequently causes flatulence and discomfort. Of the many fluid beef extracts on the market, Bovril has for some time held the foremost place in popularity. It is used in the kitchen and in the sick-room; by the busy man of commerce and by the lounger in the club; by the soldier, the sailor, and the traveller, and in many remote parts of the earth it is highly prized. Whatever the nutrient value of Bovril, and other preparations of the kind, there can be no doubt they have contributed to advance temperance; for at public bars nowadays one of them is asked for instead of spirits or other alcoholic drinks. Tropical climates do not affect Bovril so long as it remains undiluted. Brand's Essence has long held a high place in public estimation, and is a favourite preparation in the sick-room. "Lemco" is the name recently adopted by the purveyors of the well-known Liebig extract for their preparation. All the world knew the famous extract prepared by Baron Liebig, but although the name has changed we are bound to say the quality of the preparation has not deteriorated. The extract is as good to-day as ever it was.

Chichester Brand preparations have been for a considerable number of years on the market, and they are not so widely known as they might and deserve to be. Shippam, of Chichester, manufactures these products, and those we have tried—the beef-tea and chicken jelly—are excellent, appetising, and easily digested.

Maconochie's preparations are pleasant to look at, agreeable to taste, and leave a sensation of cleanliness of the palate, very different to the mawkishness and burnt-beefy flavour which hangs about the mouth after some of the similar preparations in the market. The calves-foot jelly is specially good, and is relished by children; it possesses the great advantage of being ready for use. The essence of beef is a wholesome preparation. Messrs. Maconochie have endeavoured, and with success, to supply a compressed meat tablet, under the name of Vitox. The tablet is pleasant to taste, satisfying and sustaining, and contains as much nourishment as it is possible to get into so small a bulk. There are other well-known preparations of similar nature to the above, and most people have a preference for this or that jelly, extract, or essence. An apparent drawback to all these "solidifying" preparations is that they become fluid in warm climates. This is not really a drawback, as the nourishment is there all the same, and it means sipping fluid instead of jelly, but if one prefers them in a solid state, they may be put on ice, if available, or hung in a draught away from sunlight, or lowered in baskets down a well, where it is usually sufficiently cool to solidify most jellies.

Children's Food.—Of the many special preparations for infants' food, it is impossible to deal with at length. Several have been before the public for many years, and there is no fault to find with the majority of such preparations. Amongst those to be specially commended are: Neaves' Food for Infants—a carefully prepared and wholly hygienic product. The foods prepared by Savory and Moore and by Allen and Hanbury's firms have the guarantee of the names of these well-known and respected firms. The fault to be found with firms supplying food for infants is, that the majority of them pretend that artificially prepared infants' foods can, or do, take the place of milk, either in natural (human) or unnatural (cow's) form. Of special preparations for invalids and delicate people, Plasmon and Sanatogen hold deservedly high places in the public estimation. The former has been for some time in the market; Sanatogen is a more recent production, but one which has in cases of intestinal ailments such as typhoid, dysentery and sprue, become a favourite.

Business Notices.

1.—The address of the JOURNAL OF TROPICAL MEDICINE is Messrs. BALE, SONS & DANIELSSON, Ltd., 83-91, Great Titchfield Street, London, W.

2.—All **literary communications** should be addressed **to the Editors.**

3.—All **business communications** and **payments,** either for subscriptions or advertisements, should be sent **to the Publishers** of the JOURNAL OF TROPICAL MEDICINE. Cheques to be crossed The Union Bank of London, Ltd.

4.—The Subscription, which is **Eighteen Shillings** per annum, may commence at any time, and is payable in advance.

5.—Change of address should be promptly notified.

6.—Non-receipt of copies of the Journal should be notified to the Publishers.

7.—The Journal will be issued on the first and fifteenth day of every month.

Reprints.

Contributors of Original Articles will be supplied FREE with six copies of the Journal if a request accompany the MS. If reprints are required they will be supplied by the publishers, if the order is given with remittance when sending the MS. The price will be as below:—

50	Copies of four pages,		5/-;
100	,,	,,	6/-;
200	,,	,,	7/6;
50	Copies beyond four up to eight pages,		8/6;
100	,,	,,	11/-;
200	,,	,,	14/6.

One page of the Journal equals 3 pp. of the reprint.

If a printed cover is desired the extra cost will be for 50 Copies, 5/6; 100 Copies, 6/6; 200 Copies, 7/6.

THE

Journal of Tropical Medicine

OCTOBER 15, 1906.

THE PUBLIC AND THE FOOD TRADE.

THE recent gruesome disclosures of the secrets of the Chicago packing houses must have come as a rude shock to most dwellers in the Tropics, as few such can have read the articles that flooded the papers without having forced on them the disagreeable conviction that they had already largely overdrawn their account on the peck of dirt which proverbial philosophy places to the credit of every child born into the world.

In all our tropical possessions the old stager learns to utilise the resources of his adopted home, while the "griffin" may be known by his lavish expenditure on tinned "Europe stores," but there always remains a point beyond which local resources fail to meet the requirements of our European *ménu*, and to meet which, even the most seasoned veteran is driven to consume imported luxuries.

It is seldom that one can long follow the columns of our Indian dailies without meeting with a case of what is usually reported as "degchi poisoning."

The *batterie de cuisine* of the Indian cook is made up usually of copper vessels, so named, which are periodically tinned, and the gastric disturbances that are reported under the above title are popularly supposed to be due to metallic poisoning, owing to neglect to keep the cooking pots properly tinned.

Now the writer has never met with an instance in which this explanation has been verified by chemical examination of the dejecta; and it is a curious circumstance that most of these outbreaks occur after big dinner parties; on which occasions tinned delicacies always figure largely, forming as they do the Anglo-Indian's fatted calf. They are, in fact, cases of ptomaine poisoning.

In India it is quite possible to live comfortably without ever touching preserved food, but in some of our other tropical dependencies this is far from being the case. Notably, in West Africa, where from the Europoan point of view, local resources are so scanty as to leave the white population mainly dependent on preserved food.

It is practically impossible for the consumer to test the wholesomeness of articles preserved in tins, as the really dangerous changes are often imperceptible to the sense of taste, and do not result in the production of gases, so as to make the can convex at the ends, or "blown."

Food in an advanced stage of decomposition, such as that contained in a blown tin, is hardly likely to be eaten by any one, save under the compulsion of actual starvation, but, unfortunately, the consequences of eating the apparently sound articles may be far more serious than those which would result from eating the products of ordinary decompositions. It is now tolerably certain that scurvy is caused, not by want of certain vegetable acids, nor even by the lack of fresh food, in the ordinary sense of the word; but that it is due to the action of certain ptomaines which exist in a large proportion of preserved comestibles, such as salt beef, tinned goods, &c., and possibly even in stale grain.

The great Arctic explorer, Nansen, remarked with reference to an outbreak of scurvy among the men of a sledging party, who escaped starvation by utilising a store of provisions left, some years before, by some previous explorers, and who rejected the blown tins, that they would have been wiser to eat the obviously decomposed than the deceptively wholesome-tasting portions of the store, presumably under the assumption that the bacteria, which cause the subtle and dangerous changes, would be crowded out and exterminated, and their products destroyed, by those of ordinary decomposition.

Every Indian jail superintendent knows how hard it is to keep an Indian prison free from scurvy, in spite of most liberal rations of fresh vegetables, and of lime-juice. Now the only article of the prison diet which is preserved is the grain, which forms the bulk of the ration, and this is bought immediately after the harvest and stored, often in a very primitive manner, so that by the next harvest it is necessarily more or less stale. It would be interesting to ascertain if the incidence of scurvy in these institutions is seasonal.

Sponginess of the gums, such as is seen in Indian jail scurvy, is by no means uncommon among Europeans in West Africa, and it seems possible that this may be merely a manifestation of scurvy, the result of too much tinned food, and that such a condition may be an important factor in the low state of health so often noticed in residents of these colonies, quite apart from attacks of fever and other obvious tropical maladies.

It is therefore sufficiently clear that an efficient Government inspection of all preserved provisions is a *desideratum* of Imperial importance, which intimately concerns the development of many of our tropical possessions.

But it is not in the comparatively small item of preserved provisions alone that the public health is threatened by the impurity of food supplies. Milk, bread, and all foodstuffs in which adulteration is possible, are manipulated in shameless fashion.

Nor is the country producer any better than the town distributor, for it is notorious that the conditions under which milk is collected on farms, and cattle slaughtered in private abattoirs are often in the last degree revolting.

The whole business of the production and handling of food is, in fact, conducted without the least regard to either decency or cleanliness. To give a single example: Nothing is commoner, even in the best parts of the West end of London, than to see vegetables exposed for sale outside greengrocers' shops in such a position that they are accessible to any passing dog, and the baskets and their contents are actually often deeply stained with canine urine.

If this be a matter so common as to attract the notice of the casual passer by, it can hardly be supposed that the proprietors of these highly priced establishments can be ignorant of the disgusting consequences of the method they adopt to attract attention to their goods, and yet they continue to expose their customers to the certainty of having their food polluted in a most filthy manner rather than lose the chance of sale that would be involved in keeping their commodities properly protected.

That commercial rectitude and the caution of the buyer ever sufficed to protect the public against dirt and adulteration is more than doubtful, but whatever may have been the case in the "good old times," it is sufficiently obvious that stringent Government regulation of all branches of the food trade is an urgent necessity of the present day.

Another matter which calls loudly for Governmental interference is the abuse of advertisement.

It most emphatically is not a "pardonable exaggeration" to state a few teaspoonfuls of brown extractives, smelling suggestively like "secotine," represent the nutritive constituents of a cow crammed into the space of a cup, for though most buyers probably take the bare statement with some grains of salt, it may be taken as certain that they would not buy the stuff were they not persuaded that the contents of the tiny pot represent an amount of nourishment that could not possibly be concentrated to a reasonable bulk by any of the ordinary operations of domestic cookery, and as such is not the case, it is indisputable that the sellers obtain the purchase-money by false pretences, against which the public have as great a right to protection as they have against the wiles of the thimble rigger.

It must be remembered that it is especially the poor who put the most implicit trust in these lying advertisements and it is often pitiable to see hard-pressed parents and their other children pinched, to scrape together the extortionate price for some well-nigh valueless meat extract, which they fondly hope may rescue their sick child from the jaws of death: a half-crown for the amount of albumen contained in half of a penny egg!—not one whit more nutritious and far less appetising.

Not the least part of the evil is that the unfortunate victims of this system of fraudulent misrepresentation are so hypnotised by the emblazoned falsehoods that force themselves on their sight from every available wall and hoarding, that it is impossible to convince them of the uselessness of highly priced rubbish of the sort, and they will pinch themselves and defraud the butcher, baker and candlestick maker of their just dues, in order to obtain the coveted talisman, however strongly one may persuade them to the contrary.

It is as great a fraud to state that a teaspoonful of some or other concoction contains as much nourishment as a pound of beef-steak, as it is to substitute sand for sugar, and the public have as good a right to be protected against the one as the other fraud.

Were wilful misstatements of the sort dealt with as they should be by the public prosecutor, it is tolerably certain that in a very short time the trade in food specialities, which owe their popularity to nothing but advertisement and the gullibility of the public, would soon shrink to very modest dimensions, and it is hard to see why steps should not be taken to ensure so desirable an end.

AN ADDRESS

Delivered at the Opening of the Winter Session of the London School of Tropical Medicine, October, 1906.

By Colonel KENNETH MACLEOD, I.M.S., M.D., LL.D.
Honorary Physician to H.M. The King.

NEARLY three years ago, on December 7th, 1903, an address was delivered in this place by Sir Patrick Manson, whom I may without impropriety designate as the Brahma and Vishnu—the creator and sustainer—of the London School of Tropical Medicine. In that address Sir Patrick Manson described the origin, progress and prospects of the institution, and indicated its objects, achievements and requirements. The school, which was opened on October 3rd, 1899, had then completed the fourth year of its existence. An aggregate of 355 students had undergone instruction during thirteen sessions, and evidence was produced of good work accomplished in the hospital and school, and by many of its alumni who had utilised to advantage the lessons, theoretical and practical, which they had been taught.

During the three years which have elapsed since that address was delivered the school has continued to prosper. The aggregate of students who have attended during twenty-one sessions has increased to 617. Of this number 235 belonged to the Colonial Medical Service, for whose benefit and for the benefit of the colonies in which its members were destined to serve, the school was originally designed and organised, under the administration and personal initiative of that great Colonial Minister, the Right Honourable Joseph Chamberlain; 18 medical men employed by the Foreign Office, 29 officers of the Indian Medical Service, seven of the Royal Army Medical Corps, four

of the Royal Naval Medical Service, one of the Indian Civil Veterinary Department, and 33 medical officers serving under other governments passed through the School, making a total of 327, or 53 per cent. of the whole; 71 medical missionaries and 219 private students, or 290 non-officials (47 per cent.), availed themselves of the opportunities of studying tropical diseases afforded by the school. The large proportion of non-official students fully confirms the wisdom of the founders of the school in extending its benefits to all medical men, and I may add women (for the aggregate includes 40 ladies) interested in tropical diseases and mostly intending to practise in the Tropics.

The demand for admission into the school has been well maintained, and the number of entries for the present session has been, I learn, unprecedentedly large. A specially satisfactory feature in the statistics of attendance is that the number of students taking the full course of three months is on the increase. The status of the school has been strengthened by its affiliation with the University of London and the admission of tropical medicine as a sixth alternative subject for the M.D. of that University. The school course has also been recognised as entitling students to undergo examination for the Cambridge Diploma of Tropical Medicine and Hygiene. Thirty-two students of the school have succeeded in obtaining this diploma, and one student has gained the London M.D., taking tropical medicine as the optional subject. Special arrangements have been made for instruction with reference to the examination for the London Degree and Cambridge diploma. The rich experience of tropical and other diseases available in the Dreadnought Hospital has been placed at the disposal of medical graduates by the establishment of the London School of Clinical Medicine, and the services of eminent physicians and surgeons have been secured for imparting instruction in the institution.

Of the transformation which has taken place of a branch hospital into a well-equipped medical school, I have had opportunities of personal knowledge. Some twelve years ago I paid several visits to the Royal Victoria and Albert Docks' Branch of the Seamen's Hospital Society. About 20 patients were accommodated in the rooms of a small building. The patients whom I saw were seamen of many nationalities, who had been admitted from vessels trading with the Tropics, and suffered from diseases contracted in warm climates. The arrangements for their comfort and cure were excellent. The place was occasionally visited by medical men interested in tropical pathology; but no means of systematic instruction existed. There was a small room in which microscopic and bacteriological observations were made and demonstrations given of malarial and other parasites; but the work was necessarily limited to the clinical needs of the Hospital. Recently, under the guidance of Sir Patrick Manson, I visited this Institution—Hospital and School—as it now exists. The Hospital has been enlarged and can accommodate 50 patients. The new wards are spacious, clean and well ventilated, fitted with every appliance and supplied with every requisite for the treatment of the sick. The School building adjoining the Hospital, with its large and well-stocked laboratory, lecture room, museum, and library, is well adapted and provided for the instruction of 40 students; and, in addition to accommodation for the staff, provides quarters for 12 students, who are thus enabled to devote the whole of their time to their studies and practical work. The arrangements are well suited to their purpose and reflect credit on all concerned; but they are by no means complete, and the School must be looked upon as in a state of adolescence and immaturity. Effort and money are still necessary to enable it to accomplish all the good which its promoters and well-wishers desire.

It is satisfactory to know that the expenses connected with construction and organisation have, through the liberality of the Seamen's Hospital Society and the public, been fully defrayed. Conspicuous in the roll of benefactors is the name of the Honourable Bomanji Dinshaw Petit, of Bombay, who contributed 100,000 rupees to the School. Mr. Petit is evidently endowed with the liberal disposition of his family. His cousin, Sir Dinshaw Manakji Petit, Bart., among other benefactions, founded a veterinary hospital in Bombay, and contributed a large sum for a similar purpose when the Bengal Veterinary College, in whose creation I was deeply interested and concerned, was established in the year 1892. It is also gratifying to learn that the London School of Tropical Medicine is free of debt and able to pay its way; but in order thoroughly to fulfil its twofold object of education and research, the School needs further extension and development. The laboratory is not large enough for present requirements; additions are necessary for special purposes; with the exception of the Cragg's Scholarship no provision has been made for promoting and supporting research where it can most profitably be carried out, namely, in the Tropics; adequate remuneration is not given to lecturers and instructors, and the fees payable by students are high and capable of considerable reduction.

For these and other purposes more money is wanted. Sir Patrick Manson, in the address to which I have referred, estimated that £100,000 were required to place the School on a satisfactory and permanent basis. I understand that of this sum about £40,000 has been received. The remaining £60,000 would form an endowment which would expand the operations and enhance the usefulness of the School. Surely the wealthiest city and busiest port in the world may reasonably be expected, when the want is known, to contribute handsomely to the support of an institution whose work is designed to mitigate the loss of health and life, which interferes so greatly with the industry and commerce of our tropical colonies and dependencies, and causes such a waste of time, labour and money. The wealth of London and of England is largely drawn from the colonies and from the carrying trade connected with them; and any agency or institution which ministers to the promotion of health and prolongation of life, and thereby cheapens production, barter and transport, is deserving of encouragement and support. So that motives of benevolence and self interest combine to advocate the claims of the School to such liberal endowment, as to make it worthy of the city and country, and thoroughly competent to carry out those objects and operations whose aim is to benefit humanity and promote civilisation.

The necessity of special instruction in the diseases of tropical countries does not require argument or proof. As these countries have their peculiar flora and fauna, of which no general teaching of botany and zoology or special study of the plants and animals of temperate regions can supply a knowledge, so there are in the Tropics special manifestations and modifications of disease regarding which pathology and nosology, as taught in the medical schools of this country, afford very little information. The analogy is by no means a strained one, for the pathology of the present day is largely concerned with botany and zoology, and includes a study of vegetable and animal life. This fact has been widely recognised in the scheme of instruction arranged in this school. Through the liberality of the colonies the subjects of protozoology and helminthology have been added to the curriculum of study—a novel and important departure which merits commendation and imitation. The study of vegetable microbes is included in that of the diseases with which they are associated; but to complete the teaching of parasitology there is one subject which ought to be systematically developed, namely, pathological entomology. Insects, more especially blood-sucking insects, the mosquito and tsetse-fly for example, have been found to fulfil an important function in the conveyance of infective disease, and the harbouring and transmission of disease germs, and knowledge on this subject imperatively claims to be imparted and extended. Recent observations indicate that leprosy is spread by insect agency, and cholera, enteric fever, and plague are very probably similarly transmitted; but on these and other cognate points additional light is required. I trust, therefore, that a pathological entomologist will, in the early future, be added to the staff of the school.

The trend of modern investigation and thought has forced into the forefront the fascinating subject of comparative pathology, which has followed naturally but somewhat tardily on comparative anatomy and physiology. The researches of recent years, conspicuously as regards tropical diseases, have revealed a community of suffering and a reciprocity of infection and protection between man and the lower animal creation which have invested medical science with fresh interest and endowed it with larger power. In this connection it is pleasing to note that an agreement has been concluded between the London School of Tropical Medicine and the Royal Veterinary College, Camden Town, by which students of either institution may attend the other; and an interchange of demonstrations has been arranged. The inquiries and experiments which have made comparative pathology what it is, have been beneficial to both man and beast, and are capable of becoming more so—a point which is strangely overlooked by those who, from laudable but short-sighted motives, decry some of the methods by which our knowledge of influences, disabling and destructive, affecting animal life, is advanced. Physiologists and pathologists have been accused of callous selfishness and cruelty in subjecting the lower animals to experiment for the purpose of furthering medical science and improving medical art; but in investigating tropical diseases, men have, themselves, in numerous instances, incurred risks to health and life without hesitation. The true causation of yellow fever was discovered through the agency of volunteers who readily subjected themselves to dangerous hazards in disproving the old doctrine of infection by fomites, and proving the fact of communication by mosquitoes. In working out the problem of malaria, human experiment has also been largely resorted to, as in the two crucial tests which were applied by members of this School. In 1900, Drs. Sambon and Low braved the perils of the Roman Campagna during the fever season, and by protecting themselves from mosquito bites escaped the maladies which prostrated the unprotected inhabitants of that malarious tract; and in the same year Patrick Thurburn Manson and George Warren contracted ague in London by allowing themselves to be bitten by mosquitoes which had been fed in Rome on plasmodium-infected blood. Similar risks, fatal in some instances, have been run, in investigating Malta fever, cholera and plague, and among recent medical martyrs the names of Lazear, Myers, Dutton and Tulloch, deserve special and regretful record. The study of comparative pathology is peculiarly needful in the Tropics where, under a different environment, life, and conspicuously parasitic life, is more exuberant than in temperate regions, and the struggle between the higher and the lower life, between the things and forces that make for development and construction, and those that make for decadence and destruction, is more keen and stringent.

The facts and laws of comparative pathology lead up to the higher reaches of transcendental biology and furnish new illustrations of the law of survival of the fittest, which the genius of Darwin formularised, and his industry so amply exemplified and established. It is important to note, however, that in this struggle the issue depends on circumstances and conditions, and is fortunately subject to the dominance of mind. The survival is not necessarily of the higher organism. In a state of uncontrolled nature the parasite is apt to obtain the mastery, the lower life to flourish at the expense of the higher; and this is specially true of the Tropics, with their luxuriant vegetation and teeming animal life. There the lower life is rampant, and the higher heavily handicapped in the contest. But when the earth is, according to the divine command, subdued for the use of man, when the primeval forest is cleared, the swamp drained, the desert irrigated, when crops serviceable to man are cultivated, and native races trained to agriculture and commerce, educated and civilised; when ignorance, poverty and filth are diminished or abolished, the parasite is at a disadvantage, physique and health are improved and life is prolonged.

The salutary effect of drainage, cultivation and cleansing, is well illustrated by the banishment of malarial disease from England. Epidemics of dysentery, which used to rage from time to time, are no longer heard of; typhus and relapsing fevers are seldom met with; plague and leprosy have receded eastward, and cholera has latterly been held at bay. In India there has also been a marked improvement in public health in consequence of undertakings such as railways, canals, waterworks and drains, which were appreciatively referred to by the Right Hon. John Morley, in his recent speech in the House of Commons.

I could, did time permit, cite numerous instances of the abatement of the incidence and mortality of fevers and fluxes in Indian towns by means of sanitary reforms, particularly vaccination, the supply of pure water and improved drainage and conservancy. I see no reason why health should be worse and life shorter in tropical than in temperate latitudes, when the conditions which affect vitality and longevity are properly understood and made the subject of proper control. In a word, what is required in the Tropics for healthy existence is reclamation—economic and sanitary—and these should go hand in hand. To this end the efforts of the whole community, not of medical men and sanitarians only, but of every member of the population, are required, and sanitary education should be made universal and compulsory. As a step in this direction, I am glad to learn that Sir Patrick Manson is preparing a catechism of tropical hygiene which he proposes to place in the hands of persons proceeding to the Tropics, and make the subject of examination as a condition of service.

The marvellous progress which has taken place during the last quarter of a century in our knowledge of the nature and causation of disease, to which the study of tropical diseases has so materially contributed, has radically revolutionised our notions regarding pathological processes. We have been compelled to widen our view and to devote more attention to the environment. Important as is the study of the host and his environment, hardly less important is that of the parasite and its environment. It is essential now that the life history of both should be worked out, and the conditions affecting both beneficially or prejudicially. Disease is no longer looked upon as a malignant entity, but as a mode of salutary resistance to noxæ; and such processes as fever and inflammation are found to be protective and curative in their purpose and effects rather than of themselves deleterious. This view proclaims the supreme importance of the study of the noxæ, as well as of the disturbances of health and function to which they give rise. The matter assumes an intenser interest when we consider that there exist in the animal body, materials whose office it is to destroy the noxæ—to kill the microbe and antagonise the poison elaborated by it. The existence of these materials and of their power, constitutes a startling instance of that adapted prevision commonly called design, which pervades nature, and whose most subtle and conspicuous manifestation is in the working of the human brain. To develop and strengthen these resistive and curative elements in the animal organisation, is one of the chief, if not the chief, object of medical science; and—greatest marvel of all—we are learning to use pathogenetic micro-organisms for this purpose, just as in the septic tank system we are employing saprophytic microbes to hasten the return of matter which has ministered to organic life, to inorganic forms, and thus to accelerate the process of decomposition, the intermediate products of which are so apt to be dangerous to health. The preparation of protective and curative vaccines and sera is engaging the attention of our most able and advanced pathologists. Even cancer, which seems to belong to the category of the infective granulomata, is being diligently experimented on from this point of view, with results which offer some promise of eventual success. The principle which underlies the great discovery of Jenner, is, after the lapse of over a century, obtaining new and remarkable applications; the familiar formulæ, *vis conservatrix naturæ* and *vis medicatrix naturæ*, are undergoing incarnation, and the intuitions of our forefathers are being converted into material facts.

In offering these observations I have, I fear, been wandering among the hazy heights of generalities; but on an occasion such as the present it seems fitting to survey the field of work as a whole—its extent, condition and capabilities—rather than examine minutely the tilth of some particular portion of it. Generalisation is a delightful exercise, and speculation, or, as Tyndall phrased it, the scientific use of the imagination, is capable, when rightly and cautiously employed, of guiding and aiding enquiry. If we can find "tongues in trees, books in the running brooks, and sermons in stones," we may reasonably expect to discover philosophy in epiphytes, wisdom in worms, and, I may add, "good in everything." But the process of generalisation is prone to become, when misused, both misleading and unproductive and is apt to be beguiling. It is so much easier to think out than to work out a problem. No better illustration of this has ever been furnished than in that land of ideals and shams—India. The genius of James Lumsdaine Bryden, in the early sixties, sought to extract pathology and etiology from arithmetical units and aggregates of units; and strange doctrines concerning pandemic waves, aerial conduction and convection, and forces cosmic, telluric and climatic, became rampant. It is fair, however, to Bryden's memory, to state that his chief achievement, the discovery of the great prevalence of enteric fever in the European Army of India, was based on an intelligent study and interpretation of cases and *post-mortem* examinations, recorded by medical officers. The *reductio ad absurdum* of Bryden's visionary views was accomplished by James Macnab Cunningham, who, with a logical Scotch mind, showed unwittingly how they led to scepticism and nihilism. But, ever since the arrival of the English in India, there have been men who investigated the diseases of the country by clinical methods. The names of Johnson, Twining, Annesley, Webb, Martin, Goodeve, Morehead, Chevers, Carter, Moore and Fayrer, merit remembrance. Their work possesses great value, but it was too exclusively devoted to the subject of disease and the environment was neglected. A new era of systematic, practical observation, was opened by the deputation of Timothy Lewis and David Douglas Cunningham, in the year 1870, to investigate cholera by the methods which they had learned in the Army Medical School, Netley, which was an early pioneer in the special study of tropical diseases, and in which, from first to last, clinical and practical systems of study were followed. It is education of this sort that has fitted men like Bruce, Ronald Ross, Leslie, Roberts, Leishman, and Donovan, to accomplish work which has revolutionised tropical medicine, and, under the stimulating influence of Professor (now Sir) Almroth Wright's instruction, numerous observers, among whom I may specify the names of Lamb, Rogers, Liston, Douglas,

Bannerman, Buchanan, Christophers, James, and Greig, are now engaged in fruitful researches in India. Lewis and Cunningham did excellent work in many directions; but the methods which have been instrumental in adding so materially to our knowledge, particularly staining, pure cultivation and animal experimentation, did not come into full use in their time. The Government of India has now responded to the demands of modern medical science, and has resolved to establish laboratories for clinical aid and pathological research throughout India. Many of these are already in existence and active operation. The Pasteur Institute, at Kasauli, has been converted into a central research laboratory, under the direction of Lieut.-Colonel Semple, another disciple of Wright's; the King Institute at Guindy, in Madras, under Lieut. Christophers, is fully fitted for vaccine bacteriological and pathological investigations; the plague research laboratory in Bombay, organised by Haffkine, and Hankin's laboratory at Agra, are available for all kinds of inquiries, and Lingard's laboratory at Muktesar is devoted to similar studies in veterinary pathology. Other institutions of the same kind are being established, and in time every large hospital in India will no doubt have its laboratory.

To those who are about to commence their studies in this school I offer hearty congratulations on the excellent opportunities they possess for fitting themselves for the responsible duties of their future career. My own experience enables me to bear thankful testimony to the priceless benefit which I derived during my twenty-six years' service in India, from the vivid pictures of tropical disease which Maclean presented to us at Netley, and the sound lessons conveyed to us in the lecture-room, wards and laboratory, regarding their prevention and treatment. Since the year 1865 our knowledge of tropical diseases and of the means by which they are most profitably investigated has undergone a startling advance. I realised this acutely when, in 1897, I was appointed to occupy the Chair of Military and Clinical Medicine, which Maclean had so ably filled; and so rapid did this advance continue to be that, during my eight years' tenure of that office, I found it necessary from term to term materially to alter my lectures—to modify, to cancel, and to add. You are fortunate in being inheritors of the great accession to our knowledge of tropical pathology and hygiene which recent years have brought. There is hardly a subject which has not undergone illumination. Malaria, cholera, plague, leprosy, yellow fever, Malta fever, filariasis, ankylostomiasis, trypanosomiasis, kala-azar,—to catalogue some brilliant examples—have been investigated with diligence and success. Their special causes have been demonstrated, and important indications for their prevention and treatment supplied. But great as have been the triumphs much work still remains to be done on these and other subjects. The more we know the more we want to know. As the circle of knowledge widens the horizon of ignorance also seems to extend. The etiology of dysentery is still very obscure, and the relation of its different forms to hepatic abscess; we are still in ignorance regarding the causation of beri-beri, sprue, dengue, epidemic dropsy, infantile biliary cirrhosis, and many of the infective granulomata; and the strange terms, ponos, goundou and ainhum, require pathogenic explanation. Why is the native of India relatively immune to the infection of enteric fever? Why do dysentery and beri-beri break out in the lunatic asylums of temperate regions, while the general population remains exempt? What is the relation between hill diarrhœa and sprue, whose symptoms are almost identical; and between kala-azar and Delhi boil, which appear to be caused by the same micro-organism? Why is the embryo of filaria nocturna absent from the blood in elephantiasis, which appears in the great majority of cases to be caused by filarial infection? These are a few examples of problems which still await solution. This school has already sent forth many earnest and successful workers, among whom Low, Daniels, Castellani, Bentley, Wise, Balfour and Philip Ross, deserve special notice; and the inspiration and training which you will imbibe and undergo here will stimulate and qualify you to follow their footsteps. The assimilation of knowledge is very precious, but the acquisition of aptitude for increasing knowledge is much more so. But, while discovery and invention are objects of high and laudable ambition, few are gifted with the power of productive original research, and it is very remarkable how meagre are the really permanent contributions to science of even the most gifted. Still it is open to every one to aid in some manner and measure, however humble, in the building of the temple of medicine. Permit me finally to remind you that the main purpose of your lives, as practitioners of the art of medicine, as it is the prime motive and glory of your profession, is to promote the welfare of man, to prevent and cure disease, to relieve suffering and prolong life. In striving to accomplish these ends you will earn gratification and gratitude, even if you fail to gain fame or fortune.

A vote of thanks to Colonel Kenneth McLeod was proposed by Mr. Edmund Owen, F.R.C.S., and seconded by Sir Frederick Young, K.C.M.G.

Sir George Denton and Fleet Surgeon P. W. Bassett Smith, R.N., also spoke.

A large number of people were present, including Professor Blanchard and Dr. P. Joly, from Paris.

The Annual Dinner.

The London School of Tropical Medicine and the London School of Clinical Medicine held their annual dinner at the Hotel Cecil on October 8th, 1906. Sir Wm. Hood Treacher, K.C.M.G., occupied the chair.

Amongst those present were:—Prof. Blanchard, Paris; Inspector General H. M. Ellis, K.H.P., Medical Director General of the Navy; Surgeon General A. M. Branfoot, C.I.E., President of the Medical Board of the India Office; Col. Kenneth McLeod, I.M.S.; Sir William Bennett, K.C.V.O.; Sir Patrick Manson, K.C.M.G.; Sir Dyce Duckworth; Sir John McFadyean; Sir Francis Lovell, C.M.G., Dean, London School of Tropical Medicine; Commander G. Hodgkinson, R.N.; Fleet Surgeon P. W. Bassett-Smith, R.N.; Percival A. Nairne, Esq., Chairman of the Committee of Management, S.H.S.; H. J. Read, Esq., Colonial Office; J. H. Batty, Esq.; A. E. Aspinall, Esq.; E. R. Davson, Esq.; Prof. W. J. Simpson, Prof. R. T. Hewlett, Dr. F. H. Anderson, Dr. Oswald Baker, Dr. Robert Boxall, Dr. H. Burrows, Dr. C. C. Choyce, Dr. C. W. Daniels, Dr. J. Mackenzie Davidson, Dr. Andrew Duncan, Dr. W. Fox, Dr. J.

Galloway, Dr. Russell Howard, Dr. P. Joly (Ministry of Marine, Paris), Dr. A. Ernest Jones, Dr. T. D. Lister, Dr. G. C. Low, Dr. Stephen Mayou, Dr. Guthrie Rankin, Dr. L. W. Sambon, Dr. G. E. Waugh, Dr. Russell Wells, Mr. Malcolm Morris, Mr. James Cantlie, Mr. L. V. Cargill, Mr. K. W. Goadby, Mr. A. Lawrence, Mr. L. H. McGavin, Mr. P. Michelli (Secretary).

The following telegram was read from the Duke of Marlborough, who was to have taken the chair: "Much regret unable to preside at this evening's dinner. Trust that both branches of school may receive that public support and recognition which their untiring efforts and skill so richly deserve."

The toast of "The King" having been honoured,

The Chairman proposed the toast of "The London Schools of Tropical and Clinical Medicine." He said that during his service in the Eastern Tropics, extending over some thirty-three years, he had come across a number of doctors who had had the advantage of passing through the school, and he had always found them to be keen officials, devoted to their important work, kindly, hospitable and charitable. For a considerable time he had taken a keen interest in the London School, which owed its origin, in the year 1899, to that great Colonial Minister and Imperial statesman, Joseph Chamberlain, whose restoration to health and return to active political life men of all parties anxiously desired. He had done his best to support and encourage in every way the foundation of an institute for medical research in the Malay States, the idea of which emanated from the fertile brain of that distinguished Colonial administrator, Sir F. Swettenham. The London Tropical School had now a hospital with 50 beds, and there was accommodation in the laboratory for 40 students. Nearly all of these places were occupied, and it was evident that further accommodation would be necessary in the future. Altogether 617 students had passed through the school. The Tropical School, although its financial position was sound, he would remind them that it was essential that a capital sum should be obtained to form an endowment by which the teachers in the school be adequately paid and full facilities afforded for research.

The London School of Clinical Medicine, which was a new organisation, had been established for the purpose of supplying the increasing demand for post-graduate teaching in London. It was the aim of the Clinical School, with the aid of the Committee of the Seamen's Hospital Society, to provide in London such teaching as might compare with that of any other centre of education.

Sir Patrick Manson, in replying to the toast, said that not many years ago some wise men shook their heads over the London School of Tropical Medicine, and a great many unwise men spoke with contempt of it. The result, however, had certainly not justified the prognostication. At present the school was recognised by the University of London and by the Colleges of Physicians and of Surgeons as a *bonâ fide* and valuable teaching institution. Through their school important contributions had been made to the advance of medical science, all having more or less a bearing on human pathology and human disease.

Drs. Castellani, Leiper and Wenyon, had each contributed during the past year important original observations, and many other old students of the school had added to our knowledge of tropical disease. Lack of funds prevented the school undertaking all that was desired and desirable in the elaboration of discoveries and observations; laboratories, and specially qualified men to work in them were imperative; and the equipment could not be considered complete until an entomologist was added to its strength.

Sir Dyce Duckworth responded to the toast of the London School of Clinical Medicine. He stated that this important post-graduate school was founded by the energy and enterprise of the Committee of the Seamen's Hospital, who had already laid the country under a deep debt of gratitude for the School of Tropical Medicine. It is to be hoped that the London School of Clinical Medicine will have a great future, and that everything the medical staff and teachers could do to develop the School would be carried out in a whole-hearted manner.

Professor W. J. Simpson proposed the toast of the orator of the day, "Colonel Kenneth Macleod." He stated that neither in India nor at Netley would Colonel Macleod's work be forgotten. He had retired after an honourable and distinguished career, and amongst the great men who had illuminated the Indian Medical Service, or who had filled the chair of Military Medicine at Netley, Colonel Macleod's name would occupy a foremost place.

Colonel Kenneth Macleod, in reply, said that the London School of Tropical Medicine was a great school, one that the country might be proud of, and the people throughout the Empire ought to be thankful for the beneficent work it had done and is doing.

Sir William Bennett proposed the toast of the "Visitors," and accorded a special welcome to Professor Blanchard, who at all times had shown so kindly a disposition towards the Tropical School.

Professor Blanchard (Paris), in reply, stated that the London School of Tropical Medicine had stimulated the teaching and investigation of tropical diseases in the British Empire, and set an example which was being followed by all civilised countries. In a brilliant speech Professor Blanchard congratulated the British Schools of Tropical Medicine upon their work.

Inspector-General Ellis, Director-General of the Medical Department of the Royal Navy, said that they were well aware of the enormous benefits they had received from the teaching of the Schools of Tropical Medicine in London and Liverpool.

Surgeon-General Branfoot, C.I.E., on behalf of the Indian Medical Service, said he was glad to see that officers of the Indian Service availed themselves whenever possible of the teaching of these great schools.

Mr. P. A. Nairne, Chairman of the Seamen's Hospital Society, proposed the toast of "The Chairman." Sir Wm. Treacher Hood was one of many Englishmen who had guided the destinies of the British Colonies to success, and amongst the great governors of our colonies the Chairman took a high place.

The Chairman, in acknowledging the toast, paid a well-deserved tribute to Mr. P. Michelli, the Secretary of the Seamen's Hospital.

List of Students at London School of Tropical Medicine, October 8th, 1906:—

Indian Medical Service.—Major R. H. Castor, M.R.C.S., L.R.C.P.; Major S. A. Harriss, M.B., C.M. (Edin.), M.R.C.S., L.R.C.P., D.P.H.(Camb.); Major J. B. Smith, M.B., B.A., M.Ch.(R.U.I.)

Colonial Service.—E. W. Graham, M.B., C.M. (Glasgow); H. W. Gush, M.B., Ch.B.(Edin.); F. I. M. Jupe, L.S.A.; H. McG. Newport, L.R.C.P. & S.; W. B. Orme, M.R.C.S., L.R.C.P.; P. H. Pereira, M.B.(Madras), 1905, M.R.C.S., L.R.C.P.; A. B. S. Powell, L.R.C.P. & S.(Edin.); C. C. Robinson, M.B. (Lond.), M.R.C.S., L.R.C.P.; R. F. Williams, M.B. (Camb.); W. J. Von Winckler, M.R.C.P., L.R.C.P., L.S.A. (Member Inner Temple, London).

United States Army.—Capt. J. M. Phalen, U.S. Army, M.D.(Univ. of Illinois).

Missionaries. — W. Cammack, M.D.(N.W.Univ., Chicago), and Mrs. W. Cammack, M.A., M.D.(State Univ., Iowa), American Board of Missions; C. F. Fothergill, M.R.C.S., L.R.C.P., M.B., B.C.(Camb.), B.A.(Camb.), Church Missionary Society; Hannes Heikinheimo, L.M., Helsingfors, Finland, Missionary; R. Howard, M.B., B.Ch.(Oxon)., M.A., University Mission; G. F. Stooke, L.R.C.P. & S.(Edin.), L.F.P.S. (Glasgow), Church of Scotland Mission.

Private.—Otto Bluhme, M.D. (Havana); E. P. Caropoulos, M.D. (Athens); Miss B. Cunningham, M.B., Ch.B.(Edin.), L.M.(Dublin); A. MacDonald Dick, M.B., Ch.B.(Edin.); P. R. Egan, M.D. (Columbia, New York); T. Giordani, M.D. (Rome); J. G. F. Hosken, M.R.C.S., L.R.C.P.; Miss Mary Kidd, M.B. (Lond.); J. A. Knebel, M.D. (Utrecht and Amsterdam); E. J. Maxwell, B.A.(Camb.), M.B., B.C. (Camb.), M.R.C.S., L.R.C.P.; Miguel Paz, M.D. (Guatemala); H. B. G. Newham, M.R.C.S., L.R.C.P., D.P.H.(Camb.); A. H. Reid, M.B., C.M.(Edin.); P. M. Rennie, M.B., Ch.B.(Edin.); F. O. Stoehr, M.B. (Oxon); F. M. Suckling, M.B., Ch.M.(Sydney); K. Raman Tampi, B.A. (Madras), M.B., Ch.B.(Edin.); W. A. Trumper, M.R.C.S., L.R.C.P.; J. C. Venniker, M.D.(Durham), F.R.C.S.E., M.B., B.S., D.P.H. (Durham), M.R.C.S., L.R.C.P.; W. W. Woolliscroft, M.R.C.S., L.R.C.P.

Indian Medical Service 3, *Colonial Service* 10, *United States Army* 1, *Missionaries* 6, *Private Students* 20; *Total* 40.

Obituary.

COLONEL ALEXANDER CROMBIE, M.D., C.B.

It is with the deepest sorrow and regret we announce the death of Colonel Crombie, C.B., late of the Indian Medical Service, and a member of the Advisory Committee of the Journal of Tropical Medicine. Although the obscure illness from which he suffered, and which confined him to bed for nearly two years, prepared his many friends for the end, yet his death came suddenly and unexpectedly, at a time when he was being taken abroad for the winter. He died at an hotel in Dover, on his way to the Continent. By Colonel Alexander Crombie's death, the profession loses one of its brightest ornaments. A clinician of the first order, he brought to bear on his work not only a keen intellect, ripened by a vast experience, but also an attractive personality, full of sympathy, generosity and kindness, which inspired confidence in those who consulted him, and endeared him to all his friends. Born in Fife some sixty-one years ago, of a good family, his childhood was spent in the country, where the fields and hills and heather implanted a passion for poetry and flowers, which continued throughout his life, and made him a charming companion to his most intimate friends. After a distinguished career at Edinburgh University, he graduated with honours in 1867, and settled in practice near Berwick-on-Tweed. Later, however, he gave up practice and entered the Indian Medical Service, in which he soon distinguished himself, and was rewarded by being appointed successively to some of its more important civil-surgeoncies, such as those of Rangoon and Dacca. On his transference to Calcutta he became Surgeon-Superintendent of the European General Hospital, a position which not only placed him at the head of the most important hospital in Calcutta, but also brought with it a large consulting practice. He retained this position until he retired in 1898, and was appointed a member of the Medical Board at the India Office. It was in his capacity as a member of this Board that he was deputed to the Army Board to medically examine officers starting for and returning from the South African War, and it was for this service, which entailed an enormous amount of work, together with the good service he had done in India, that he was decorated with the Order of the Companion of the Bath. Gradually he was acquiring a large consulting practice in London in tropical diseases, and there is no doubt that if he had not been attacked by this untimely illness, the pain and suffering of which he endured with so much patience and fortitude, his special knowledge of tropical diseases would have given him one of the largest consulting practices in London. Colonel Crombie was lecturer on tropical diseases in the Middlesex Hospital, and also at the London School of Tropical Medicine. He was an excellent lecturer, and the loss which these schools have sustained is very great. His contributions to medical literature are particularly valuable, coming as they do from a keen and experienced observer. Among these may be mentioned his observations on the normal temperature of Europeans and natives in India, in which he showed that natives of India had a higher temperature than Europeans, and Europeans in India a higher temperature than Europeans in temperate climates. His paper on the unclassified fevers of the Tropics is also a memorable one, in that it foreshadowed much that has been since verified by microscopical research and discovery. Colonel Crombie leaves a widow, a son and two daughters to mourn his loss. Our deepest sympathy is with them in their sad bereavement.

Notices to Correspondents.

1.—Manuscripts sent in cannot be returned.

2.—As our contributors are for the most part resident abroad, proofs will not be submitted to those dwelling outside the United Kingdom, unless specially desired and arranged for.

3.—To ensure accuracy in printing it is specially requested that all communications should be written clearly.

4.—Authors desiring reprints of their communications to the Journal of Tropical Medicine should communicate with the Publishers.

5.—Correspondents should look for replies under the heading "Answers to Correspondents."

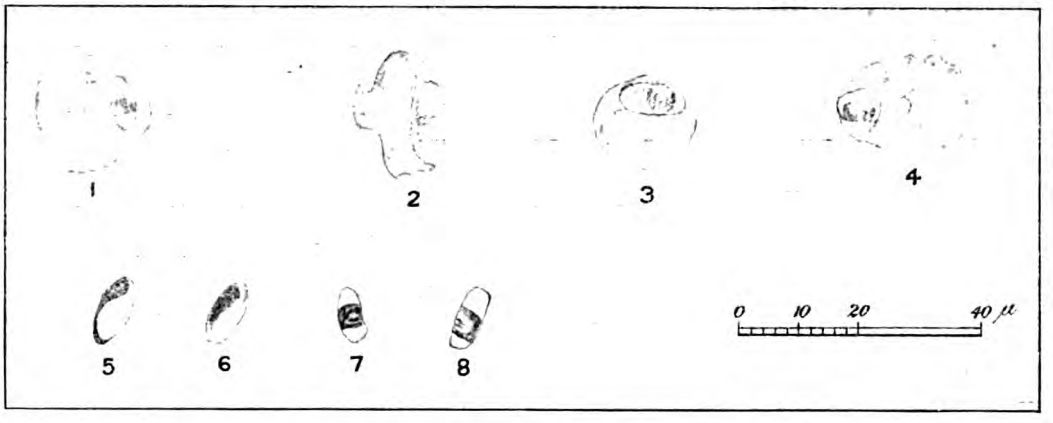
Original Communications.

NOTE ON A LEUCOCYTOZOON FOUND IN *MUS RATTUS* IN THE PUNJAUB.

By Colonel J. R. Adie, I.M.S.
Ferozepore, India.

Note.—By Major Ross, C.B., F.R.S., Professor of Tropical Medicine, University of Liverpool.

This report was handed to me by Colonel Adie, I.M.S., last July, for publication in the forthcoming number of the Thompson Yates and Johnston Laboratories' Reports. Owing, however, to the delay in this publication, I have not been able to give effect to Colonel Adie's wishes. I have now requested the Editor of the Journal of Tropical Medicine to publish the paper in view of the interesting article by Dr. Cleland in that journal for October 1st.



1, 2, 3, 4, show the parasite in the leucocyte. 5, 6, 7, 8, represent parasites with well-stained nuclei, showing the peculiar arrangement of the chromatin.

Last January, while engaged in examining the peripheral blood of a series of ordinary house rats (*Mus rattus*) in Ferozepore (Punjaub), I came upon a film which showed something unusual—a parasite in a leucocyte.

I have not yet had an opportunity of studying this parasite in the fresh state, and the description which follows is derived from specimens met with in many films from more than one rat, the films being stained by the long Romanowsky method.

The appearance of an affected leucocyte is striking, and an observer cannot fail to have his attention drawn to it, even with a ⅔ obj. and No. 4 E.P. In fact, by this combination, one can most easily recognise a specimen in the film.

The parasite is not, so far, found in all varieties of leucocytes, but only in those which might be classified, according to definition of terms, as transitionals and mononuclears.

Its shape is uniformly oval, and the nucleus well-defined. It appears to have a well-marked and well-stained cell wall. The protoplasm is either uncoloured, or sometimes shows a faint pink staining, especially towards the periphery. Not infrequently, faintly stained red dots, six to twelve in number, are seen in the neighbourhood of the nucleus, and, occasionally also at one end of the oval. In one specimen the entire protoplasm showed faint stippling.

The nucleus is peculiar. The shape is most often quadrilateral, with rounded angles. It occupies the whole, or nearly the whole, width of the cell, is situated rather nearer one end, and what is very striking, generally shows transverse striation. These striæ are not always parallel, but may appear as curious patterns. The above seems to be the appearance as seen on the flat. At other times, the nucleus is oval, or crescent-shaped, or obliquely pear-shaped; and this seems to be the side view.

The outline of the organism can be clearly made out, even when the nucleus of the leucocyte is quadrilateral, or annular, or approaching the polynuclear shape.

The length of this leucocytozoon is from 9·8 to 13 microns, and breadth from 5·2 to 6·5. The average dimensions are 11·7 by 5·6 microns. The nucleus, when quadrilateral, is about 5 or 6 microns square.

No pigment has been seen either in the parasite, or in the affected leucocyte. Only one free specimen has been met with.

In a series of thirty-nine rats examined, the leucocytozoon was met with in eight, or 20 per cent.; and in the same series, trypanosomes were found in sixteen, or 41 per cent. The leucocytozoon was found only in cases where trypanosomes were also found. In other words, half the rats harbouring trypanosomes were found to be harbouring the leucocytozoon. Roughly speaking, the numbers of the two parasites corresponded, that is, when trypanosomes were numerous, leucocytozoa were numerous; but in three cases, trypanosomes were very numerous and no leucocytozoa were found.

Through the kindness of Captain Liston, I.M.S, of Bombay, I have seen some of his preparations of spleen smears of rats, taken in the Punjaub when he was investigating plague. He also noticed this leucocytozoon. In his stained smears the parasites look

oval, and the nucleus oval too. But I could not make out any particular nuclear structure. Nor is one able to say if the leucocytozoon has any relation to trypanosomes, as the latter are not common in rat spleen smears. The different appearance of the nucleus in Captain Liston's and my specimens may be accounted for by the manner of spreading; his being a spleen smear, and mine a blood film.

It has been noted that the parasite inhabits a particular kind of leucocyte—a large cell, whose nucleus is never seen round, and never multiple, with connecting strands. It is an oval, or an indented oval, or a ring, or it has an irregular shape. The protoplasm is hyaline. It is not easy to make a count of these films, as the greatly-varying shapes of nuclei make it difficult to classify the cells as polynuclear, or transitional, or mononuclear. There is also the difficulty of intermediate forms. It seems the rat, normally, has a greater number of transitionals and mononuclears, proportionally, than man; so that it becomes necessary to separate the transitionals in making counts.

The following table shows counts in rats' blood (*a*) without any parasites, (*b*) with many trypanosomes, and (*c*) with many trypanosomes and many leucocytozoa.

	a No parasites	*b* Trypanosomes only	*c* Trypanosomes and Leucocytozoa
Polynuclears ..	22·3	25·6	25·
Transitionals ..	17·	17·6	15·7
Mononuclears ..	14·5	21·6	7·7
Lymphocytes ..	44·4	32·6	51·
Eosinophiles ..	1·6	2·3	·6
Basophiles ..	·2	·3	·0

Bentley and James [1] have found a leucocytozoon in the dog in India. James states that it almost invariably invades the polynuclears. Some of his figures are of leucocytes, whose nuclei seem to point to the transitional type, but the protoplasm is depicted as granular. James's *Leucocytozoon bentleyi* is 10½ by 5¼ microns. Its shape is not quite the same as this rat's parasite; it may be associated with filaria and piroplasma.

Christophers [2] describes a somewhat similar parasite, *Hæmogregarina gerbilli*, in the Indian field rat. It is partly curved on itself, and enlarges the *red blood corpuscle* from 5½ to 6½ microns to 10 by 7 microns.

Balfour [3] describes a hæmogregarine in the desert rat, Jerboa. It may be free, or in the remains of a red cell—size 5·6 to 7 by 1·4 to 2·8 microns. The free form is 3 red-cell-diameters long, and 2·8 microns wide. He states incidentally, "I have recently discovered what seems to be the same parasite in the mononuclears of the Norway rat (*Mus decumanus*) in Khartoum. It is probable it exists as a leucocytozoon in the rodents." From the figure of this latter, the parasite is seen to have a close resemblance to the Punjaub specimen, and to inhabit a leucocyte which may be counted transitional or mononuclear.

Patton [4] has recently described a leucocytozoon in the mononuclears of the palm squirrel, both in the cells and free. He notes the large number of mononuclears in a film, but does not speak of transitionals. His leucocytozoon also shows a curled tail. Free forms are common, 13 to 14 microns by 3 to 4 microns. Intracellular forms measure 10 by 5 microns. Many leucocytes have two parasites. It would appear that trypanosomes are common in this specimen of squirrel, but no particular mention is made of any relationship.

If this parasite has been hitherto undescribed, I propose the name, *Leucocytozoon ratti*.

OCCURRENCE AND HABITS OF SOME SPECIES OF HUMAN BITING FLIES BELONGING TO THE FAMILIES *TABANIDÆ* AND *MUSCIDÆ* (*GLOSSINA*), FROM THE WEST COAST OF AFRICA.

By G. C. DUDGEON, F.E.S.

(*Superintendent of Agriculture for British West African Colonies and Protectorates.*)

HAVING had the exceptional opportunity of visiting all the British West African Colonies and Protectorates during the present year, I think it probable that a few notes I made in connection with the habits of some of the biting flies found there, which attack human beings, may be of interest.

I shall make no reference to the *Culicidæ* (Mosquitos) or *Simulidæ*, but confine my remarks to the *Tabanidæ* (Horse flies) of the genera *Tabanus*, *Chrysops* and *Hæmatopota*, and to *Glossina* of the family *Muscidæ*.

The effects of the bites of these flies upon human beings are very different in severity, which point, I think calls for further investigation. It is recognised that among the *Glossina* the species *palpalis* conveys the *Trypanosoma* causing sleeping sickness, and that various other *Glossina* species in a like manner carry the parasite of the "fly disease" among cattle. In addition to this Mr. Austen now admits that there is evidence of species of *Tabanus* transmitting a disease among dromedaries in Algeria, which is also caused by a *Trypanosoma*.

I did not find that the natives in any part paid particular attention to the attacks of "tsetse" fly (*Glossina*), but in places a species of *Chrysops* was not so lightly regarded. Of this genus the one which is held in the greatest dread is a bright reddish coloured species, which had been placed, until the present, under the name of *C. dimidiatus* in the British Museum, but as my specimens included the true *C. dimidiatus* (v. d. Wulp), this red one has now to be called by a new name. As far as I was able to make

out this *Chrysops* n. sp. is known to the natives of the Calabar district under the name of "O-owe," but I did not ascertain the native name in the Warri province. Both *C. dimidiatus* and this new species were found commonly at Ologbo near Benin City. The latter species was first brought to my notice by Mr. Munro, Ex.-Engineer to S. Nigeria, when we were encamped at the last-mentioned place. The effects from a bite of *C. dimidiatus* were similar to a honey-bee's sting, causing a good deal of pain and inflammation, but from that of the red *Chrysops* even more severe with dropsical-like swelling of the limb and high temperature. My carriers appeared very much afraid of this insect and hastily dropped their loads when one came near in order to arm themselves with branches to ward off its attack; this they never troubled to do for other biting flies. Both species mentioned are somewhat similar to *Syrphidæ* (Hover flies) in appearance and, as they also hover round the person they intend to attack, their flight is not unlike that of these flies. The following are the localities where I met with them.

Chrysops dimidiatus (v. d. Wulp) Ologbo, Benin City (S. Nigeria).

Chrysops n. sp. Ologbo, Benin City, Sapele (Warri province); Odut, Uwet (Old Calabar province).

Hæmatopotas of two or three species occur commonly in the shaded paths throughout the West African Colonies, the most frequently met with being a dull black insect with mottled wings (my specimens of this have apparently become destroyed in transit). When travelling in a hammock this insect is often seen crawling slowly about the undersurface of the sun-protecting roof. The only example of the genus which I have preserved is one which was caught after having bitten a passenger upon a lower Niger steamer. Miss Ricardo has marked this "n. sp. near *Hæmatopota strigipennis*, Karsch." The bite does not appear to be serious in consequences.

Tabanus is a genus which is represented by a large number of well-marked species on the river Niger and tributaries as well as the other rivers along the coast. The approach of a *Tabanus* is made known by its loud buzzing, but the attack is not usually made by the insect at the point upon which it at first settles. In one case I witnessed *Tabanus testaceiventris* Macq. alight upon the back of a native at the wheel of a steam launch in which I was travelling, and, although it crawled over the man's bare flesh for some time, it did not attempt to bite until it had reached the outside of a vest which he wore, when it tried to drive its proboscis through the material in order to do so. The bites of all the species I met with, and which I had personal experience of, resulted in a painful swelling, which generally subsided in a few hours. The species which gave most trouble upon the creeks of S. Nigeria were *T. gabonensis*, *T. thoracinus* and *T. nigrohirtus*, while in N. Nigeria *T. tæniola*, *T. fasciatus* and *T. testaceiventris* were most conspicuous. *T. biguttatus*, of which the male is differently marked to the female, I found upon three or four occasions in a verandah in Lokoja, but it never seemed inclined to bite, only crawling slowly about flowers or verandah posts. On two occasions I took specimens of *T. obscurissimus*, upon the ground, having lost both wings. I can offer no explanation for this, although the coincidence seems rather remarkable. Some of the species of the genus are brightly coloured and the eyes of many in life are brilliant coppery green or blue. Below I give a list of the species obtained with notes concerning the colours of the eyes of some. I am much indebted to Mr. Austen, of the British Museum, and to Miss Ricardo, who is working at *Tabanidæ*, for the identifications of the specimens I collected, which will be placed in the National collection.

T. gabonensis Macq., Sapele, Odut, Ologbo (S. Nigeria).

T. testaceiventris, Macq., Ologbo (S. Nigeria): Niger River to Muraji (N. Nigeria).

T. nigrohirtus, Ricardo, Warri (S. Nigeria).

T. tæniola, Macq., Egga, Lokoja (N. Nigeria). Eyes dull green.

T. subangustus n. sp. Ricardo, Odut (S. Nigeria).

T. n. sp. *near nigrohirtus*, Ricardo, Lower Niger (S. Nigeria).

T. obscurissimus, n. sp. Ricardo, Uwet (S. Nigeria).

T. thoracinus, Pal. Beauv., Ologbo, Lower Niger (S. Nigeria). Eyes emerald green.

T. fasciatus, Fabr., Baro (N. Nigeria). Eyes coppery green.

T. latipes, Macq., Niger and Kaduna Rivers (N. Nigeria). Eyes deep blue.

T. biguttatus, Wint., Lokoja (N. Nigeria). Eyes dark brown.

T. splendidissimus, Ricardo, Ologbo (S. Nigeria).

T. n. sp. Odut (S. Nigeria).

I first met with *Glossina palpalis* in the Gambia, upon the creeks in the Kommbo province. No flies were seen until we were actually in the mangrove belt and at the water side, when numbers appeared and settled upon our clothes and upon the sides of the canoe in which we travelled. The only animals seen near here were the pack donkeys used for conveying the ground nuts to the creeks for water transport. Although the place where *G. palpalis* was in numbers was not fifty yards from where the donkeys were unloaded, no tsetse flies were attracted to them. After taking off their heavy loads the drivers hammered the muscles of the legs of every animal and pulled the joints, whereupon the donkeys rolled on the grass for a short time and appeared much refreshed. A horse suffering from the fly disease and showing all the usual symptoms was seen at Bakau, where, while examining a swamp, a tsetse fly settled upon me. Unfortunately I did not manage to capture it. In the direction of Brufut large herds of cattle were seen, and, although there were swarms of flies about them, no tsetse were seen. All the cattle were in a healthy state, but were never permitted to go in the direction of the creeks, not very far distant. At York, S. Leone, while waiting for a canoe to cross a tidal creek, Mr. Smythe, Curator of the Botanic Gardens, who was with me, was bitten by *G. palpalis* and his hand swelled to a considerable size. Although I was subsequently bitten on several occasions by *G. palpalis* and *G. tachinoides* in N. Nigeria, no such symptoms appeared in my case. The flight of the unfed insect seems to be generally short and in the form of an upward curve, dropping suddenly near the settling

point; this gives it the appearance of striking the object heavily. I have only met with the two above-mentioned species on, or upon the immediate banks of, rivers and have never seen either feed, unless in shade. Instances of places where one is likely to be bitten by tsetse flies are: inside the trouser leg below the knee, where the fly will creep up to from the boot; inside the half closed hand, upon the palm; close to the hat brim on the forehead or behind the ear. I did not notice that *Glossina* were noisy, nor could I observe any motion of wings while feeding. The occurrence of *G. palpalis* was curiously alternated with that of *G. tachinoides* on some parts of the Niger. In the lower Niger, as far up as Iddah, an almost black form of *G. palpalis* is found, from Lokoja to Baro *G. tachinoides* occurs commonly, from Egga (a few miles beyond Baro) to Muraji (junction of Kaduna river) typical *G. palpalis*, and from Muraji up the Kaduna to Dakoma *G. tachinoides* again was the only species seen. Horses are the usual method of conveyance in N. Nigeria and so long as they are kept away from the rivers do not run the risk of the fly disease. *G. morsitans* was not seen by me in N. Nigeria, but I took it upon the Volta river at about half a mile distant from the water, as well as at a place six miles north of Kumassi towards Aguna, where there was no extent of water. I think that *G. morsitans* has different habits to those of *G. palpalis* and *G. tachinoides*, and may be found at some distance from large expanses of water. Cattle are not kept upon the Volta river, and although I met with some near the place where *G. morsitans* was taken north of Kumassi, I understand that these were being brought into that town for killing, from outside the forest belt in the north. The species taken with their localities are as under:—

G. palpalis, Rob. Desv., Gambia River, York (S. Leone), Kent (S. Leone), Warri, Old Calabar, Lower Niger as far as Iddah (S. Nigeria), Upper Niger, Egga to Muraji (N. Nigeria).

G. tachinoides, Westw., Upper Niger, Baro-Lokoja, Kaduna river, Muraji-Dakomba (N. Nigeria).

G. morsitans, Westw., Pesse, Volta River (Gold Coast); between Kumassi and Ekona (Ashanti); probably also Bakau (Gambia).

NOTES ON SOME OF THE MORE OBVIOUS DISEASE CONDITIONS SEEN ON THE LINE OF THE PROJECTED LOBITO-KATANGA RAILWAY.

By F. Creighton Wellman, M.D.
Benguella, W. Africa.

The writer has from time to time published in these columns notes and papers on the diseases found in this colony, chiefly in the districts of Bihé and Bailundo. The region referred to in the following remarks, however, has not been inspected before, and indeed, so far as I can learn, has never been up to this time visited by a medical man. The most of the observations here recorded were made among the Chiyaka tribe, about 150 miles east of Lobito Bay; and are of necessity concerned mainly with those features which would strike the eye during a hasty survey of the country. It may be possible on some future occasion to present a more detailed study of the region, including results of microscopical examinations of the blood and excreta of series of the natives. The diseases mentioned are placed in alphabetical order.

Abscess of Spleen.—One case seen in which I opened and drained the abscess, the patient recovering very rapidly.

Albinism.—Two cases of complete albinism were noted.

Ainhum (see plate, fig. 9).—Two cases, neither of which showed any symptoms of leprosy.

Deformities.—Supernumerary fingers and toes were twice seen. Probably a better acquaintance with the region would reveal more, as I have seen many such cases in Africa. A case of "Siamese Twins" was reported to me, but I did not see the children personally.

Elephantiasis.—Pretty common among the blacks in the district. However, in my not large series of blood examinations I did not see embryos of *Filaria bancrofti*, although *perstans* was met several times, the man whose leg is shown in the fig. 10 (see plate) being a victim of the infection.

Epilepsy. — Very common. Many cases being brought to me for treatment, some of which showed scars from having fallen into the fire during fits.

Goitre.—Rare. Only one case seen. This region furnishes a marked contrast to the goitre-stricken areas in Bihé district.

Hernia.—Umbilical hernia is as amazingly common as in other parts of the colony. Inguinal hernia not rare. Half a dozen cases came asking for treatment.

Hypertrophy of the Breast in the Male.—A couple of cases seen. The natives are very anxious to have the growths removed, as these subject their possessors to much chaff and ridicule from their companions.

Jiggers.—*S. penetrans* as common as in other parts of the colony.

Keloids.—Common, as among all African blacks.

Leprosy (see plate, figs. 6, 7 and 8).—This disease is much commoner in the region visited than in Bihé and Bailundo districts, and severe cases of long standing were seen; leprosy is as yet comparatively rare in the districts just named.

Malaria and Blackwater Fever.—While I was not able to make in this region many blood examinations, yet both the sub-tertian and quartan parasites were seen. In looking over natives one gets the impression that the amount of malarial fever is about that seen in similar altitudes to the north. Cachexia from this cause (see plate, fig. 12) is about as common as in Bihé and Bailundo. It is interesting to note here that some thirty Boers died of blackwater fever last season at Capalla, a place formerly, I believe, considered to be quite healthy.

Myasis.—While I saw no cases of this condition yet I took many specimens of *Sarcophaga africa*, *S. albofasciata* and *Anthomyia desjardensii*, all of which I have convicted of causing myasis in this colony; besides many specimens of *Auchmeromyia luteola*, the habits of which are now so well known.

"*Ochimumusu.*"—This is a marginal ulceration of the gums common in this colony and in other parts of Tropical Africa. I made the interesting discovery of spirochætes in great numbers in the mouths of each of the several cases seen with the disease in the district under discussion. I failed to find the organism in control cases. I shall deal at length with these observations in a subsequent communication.

Sleeping Sickness and Tsetse Flies.—I am credibly informed that "fly" exists on the Kambanga, Sapa, and Solo rivers, east of Benguella along the proposed line of the railway, also on the Kuvale river and yet farther inland on the lower Cunene. The Boers state that the flies are worst about the middle of the rains (January to March), when buffalo are in the district. Although I have not yet had the opportunity of examining specimens, the fly is in all probability *Glossina palpalis wellmani* Austen, as this is the only tsetse yet found on the west coast south of the Coanza river. At Bimbash, a few hours east of Benguella, a gentleman connected with the railway informs me that nearly all the natives have died of sleeping sickness. I have elsewhere (*Journal of Hygiene*, July, 1906) discussed the probable fact that trypanosomiasis is rapidly spreading in the colony.

Tick Fever. — The "Ochihopio" (*Ornithodoros moubata*) abounds, as elsewhere, in Angola. Reports of natives and colonists here confirm my opinion elsewhere published that tick fever is commoner in the colony than it was a few years ago.

Tumours.—New growths of all varieties seem to be in the district, as elsewhere in this part of the world, fortunately rare. One striking case of tumour of the lower jaw was seen (see plate, figs. 1 and 2).

Ulcers.—These are commoner in the district than in any other region in West Africa known to me. Many of the cases of what the writer has called "subacute tropical phagedæna" go on until the underlying bones are attacked and disorganised (see plate, figs. 3, 4 and 5). In localities where such mild cases of elephantiasis as are shown in figs. 10 and 11 (see plate) are common, there were noticed large numbers of these subacute, deep-eating ulcers. Taken together with the apparent absence of *F. bancrofti* from the district, this fact suggests that the same bacterial infection may be responsible for both conditions.

Yaws. — Commoner than in Bihé and Bailundo. Spirochætæ were found in two cases; but, as the writer's investigations on this disease as it occurs in the colony are soon to be published in an official report, details need not be entered into at this time.

Explanation of Plate.

Figs. 1 and 2.—Tumour of the lower jaw.

Figs. 3, 4, and 5.—Subacute Tropical Phagedæna. (Fig. 3, a case of long standing, resulting in necrosis and fracture of the tibia. The end of the bone may be seen in the lower part of the ulcer. Fig. 4, a typical sore on the shin, also with extensive bone necrosis. Fig. 5, a piece of bone removed from the latter).

Figs. 6, 7, and 8.—Leprosy. (Fig. 6, a typical case with classical symptoms, *main-en-griffe* well shown in hands; characteristic lesions of feet, &c. Fig. 7, case with characteristic spots and patches on legs and abdomen; but these do not show well in the photograph. Fig. 8, feet of latter).

Fig. 9.—Ainhum.

Figs. 10 and 11.—Elephantiasis of the legs; early stage.

Fig. 12.—Malaria Cachexia.

TWO CASES OF FRONTO-NASAL CEPHALOCELE.

By Alexander Robertson, M.B., C.M.
Gilbert Islands Protectorate.

Ten Tekonapa, male, aged 2, admitted to Tarawa Hospital on account of tumour of the head.

Present State.—The patient is a hydrocephalic child, and does not exhibit any signs of intelligence. In the fronto-nasal region is a tumour about the size of a small rock melon, containing fluid. The weight of the tumour interferes greatly with the movements of the head, the child requiring to support the tumour in his hands. Lateral nystagmus is present in both eyes. Above the right ear, in the line of the fronto-parietal suture, is an irregular scar, an inch in length.

History.—The mother states that at birth there were two swellings, about the size of a hen's egg, on the child's head: one above the right ear, where the scar now is; the other at the root of the nose. The former burst a few months after birth; the latter gradually increased in size until it attained its present dimensions.

Operation.—Under chloroform, the skin was dissected from the tumour by means of an inverted T-shaped incision. A small aspirating needle was then introduced, and twelve ounces of clear cerebro-spinal fluid slowly drawn off. During the escape of the fluid there was no tendency to syncope, nor any appearance of blood in the exudate. Digital examination showed the absence of the glabella and the horizontal plate of the ethmoid, and marked separation of the nasal bones. The sac was then transfixed and ligatured close to the skull, and the distal portion removed. The skin incision was closed by interrupted catgut sutures. The child made an excellent recovery from the operation.

Nei Naua, female, aged 10, admitted to Tarawa Hospital on account of tumour at root of nose.

Present State.—There is a cystic tumour in the fronto-nasal region about the size of a duck's egg. It is covered by skin, which is adherent, and contains some firm, elastic substance; no cerebral pulsation is detected in this mass.

Operation.—Under chloroform, a vertical incision was made over the tumour and the skin reflected. The cyst was then incised and examined. The wall was composed of fibrous tissue $\frac{1}{8}$th of an inch thick, its inner surface being smooth and glistening. There was no cerebro-spinal fluid present. At the bottom of the cyst was a greyish mass, 2 ins. broad and $1\frac{1}{2}$ ins. thick, the outer portion firm and fibrous, the inner soft and compressible; deep pressure elicited a faint pulsation. In order to reduce the deformity as much as possible, I removed the outer portion of the mass in successive layers till I reached a point $\frac{1}{4}$th of an inch from the opening in the skull, produced by the separation of the nasal bones and the absence of the glabella; the horizontal plate of the ethmoid, in this case, was also absent. The redundant sac and skin were then ablated, and the wound closed by catgut sutures. The wound healed by first intention.

Business Notices.

1.—The address of the JOURNAL OF TROPICAL MEDICINE is Messrs. BALE, SONS & DANIELSSON, Ltd., 83-91, Great Titchfield Street, London, W.

2.—All **literary communications** should be addressed **to the Editors.**

3.—All **business communications** and **payments,** either for subscriptions or advertisements, should be sent **to the Publishers** of the JOURNAL OF TROPICAL MEDICINE. Cheques to be crossed The Union Bank of London, Ltd.

4.—The Subscription, which is **Eighteen Shillings** per annum, may commence at any time, and is payable in advance.

5.—Change of address should be promptly notified.

6.—Non-receipt of copies of the Journal should be notified to the Publishers.

7.—The Journal will be issued on the first and fifteenth day of every month.

Reprints.

Contributors of Original Articles will be supplied FREE with six copies of the Journal if a request accompany the MS. If reprints are required they will be supplied by the publishers, if the order is given with remittance when sending the MS. The price will be as below:—

50 Copies of four pages, 5/-;
100 „ „ 6/-;
200 „ „ 7/6;
50 Copies beyond four up to eight pages, 8/6;
100 „ „ „ 11/-;
200 „ „ „ 14/6.

One page of the Journal equals 3 pp. of the reprint.

If a printed cover is desired the extra cost will be for 50 Copies, 5/6; 100 Copies, 6/6; 200 Copies, 7/6.

THE

Journal of Tropical Medicine

NOVEMBER 1, 1906.

A NEW ASPECT IN THE PATHOLOGY AND TREATMENT OF LEPROSY.

ROBERT SINCLAIR BLACK, M.A., M.D.Edin., D.P.H. Aberd., Government Medical Officer, Cape Colony, contributed a thoughtful and suggestive article on the pathology and treatment of leprosy to the *Lancet* of October 20, 1906. It is doubtful if any communication in regard to leprosy since the discovery of the *Bacillus lepræ* has approached in importance the suggestions and clinical observations advanced by Dr. Black. Being clinical notes for the most part, and therefore unlikely to appeal to the advanced laboratory schools of the day, there is danger of his observations being overlooked. Dr. Black has for several years been attached to the Leper Asylum on Rodden Island, Cape Colony. In 1897 Dr. Kolle, of Berlin, commenced investigations on leprosy at Rodden Island, and directed Dr. Black's attention to the importance of the nasal passages in the clinical history and phenomena of leprosy. Working on the lines suggested, Dr. Black has arrived at important conclusions, which are at once of scientific and practical interest.

Regarding all varieties of leprosy as due to a common cause, and belonging to a single specific disease, Dr. Black found difficulty in accounting for the pronounced difference in the course and behaviour of the two well-marked varieties, viz., maculo-anæsthetic and mixed or nodular leprosy. The former seemed the more mild form of the disease, causing less disfigurement and running a much longer course; the latter appears more virulent as regards disfigurement, rapidity of development, and fatality.

He observed that (1) rhinitis is a prominent feature of almost all (or probably all) cases of leprosy in the early stages; (2) the *B. lepræ* is met with in the nasal secretion of lepers in almost all (or possibly all) early cases; (3) in mixed and nodular leprosy the nasal secretion is excessive, and the bacilli present in numbers in the secretion; (4) in maculo-anæsthetic leprosy the nasal secretion is slight, and the bacilli fewer or absent; (5) in some mixed and nodular leprotic cases, when the nose had fallen in, copious nasal secretion lessened, and the disease became practically of the mild form attendant upon maculo-anæsthetic leprosy. He concludes from these observations: (1) That the maculo-anæsthetic is a mild form of leprosy attended by an early manifestation of a nasal ulcer, with some nasal secretion in which the *B. lepræ* is present, but from which the bacillus disappears in time, owing to the nasal ulcer healing, and the nasal secretion lessening or wholly drying up; (2) that mixed or nodular leprosy is attended by extensive ulceration, and a growth of granulation tissue in the nasal mucous membrane extending from thence into the naso-pharynx and to the cavities which communicate with the nose, thereby leading to distortion of the features. The nasal secretion in such cases is copious and charged with large numbers of the *B. lepræ*. As regards manifestations, Dr. Black is of opinion that mixed nodular leprosy is simply maculo-anæsthetic leprosy plus the infiltration and œdema of the subcutaneous tissues in various parts of the body, caused by the more active *invasion of the B. lepræ*.

"I think that there can be hardly any doubt that leprosy in its early stages begins as a small ulcer on some part of the extensive nasal mucous membrane. We know quite well from our clinical experience of the disease that leprous ulcers in favourable circumstances tend to heal. There can therefore be little doubt that a person can suffer from a leprous ulcer in the nose that may heal and pass entirely away. This is the explanation of the maculo-anæsthetic cases. They have had nasal ulceration which has passed away, in some cases leaving perhaps a cicatrical shrinking of the nasal septum, but during the time the ulcer existed leucocytes or white connective tissue corpuscles got detached from the ulcerating spot and along with the bacilli which they were attempting to devour were carried by the blood stream and lodged in various situations in the peripheral nerves, where they got entangled, and the bacilli then proceeded to grow, causing pressure on the fine nerve fibrils, and consequently setting up nutritive changes in the skin which these axis-cylinders supplied, thus causing the patches of discolouration and anæsthesia."

"In the nodular and mixed cases the progress of the disease is quite different. Instead of the nasal ulcer healing up it proceeds to grow apace, causing extensive destruction of the nasal mucous membrane, causing it to swell up and ultimately attacking the nasal bones themselves."

Dr. Black's observations help us to understand with something like precision the difference between mild and severe forms of leprosy, and to draw attention to the nose as being probably the primary focus of infection and the seat of the primary ulceration. The early rhinitis assumes an importance hitherto disregarded, for in the recognition of this seemingly trivial nasal catarrh may lie the key of the problem. It is seldom lepers apply for medical treatment whilst merely the symptoms of an excessive cold are in progress; did they do so, the examination of the secretion for *B. leprœ* would clear up the diagnosis and give opportunity, were the bacillus found, of treating leprosy by rational methods. There is no reason why the festering nasal sore, which is the real cause of the complaint, should not be attacked by curetting, by nasal douches and by other means, so that the source of infection may be done away with, or the potency of infection diminished. Even in more advanced cases the treatment of the nasal condition affords some hope of doing good and limiting or preventing further infection of the body generally by the destruction of the infecting organism at its source. Dr. Black has placed the treatment (and the phophylaxis) of leprosy on a rational plane; he has raised it from the mere "treating of symptoms as they arise," and of empiric treatment generally to a rational if not to a scientific platform; he has brought hope to the leper, and has taught us to divorce leprosy from the mystery which surrounds it, and to rank its manifestations alongside of other ailments arising by primary sores and other foci of infection.

SANITARY ORGANISATION IN INDIA.

THE Committee that met at Simla to consider the constitution of the new service of sanitary engineers has completed its work, and its recommendations will now be considered by the Government of India. The result of its deliberations will be awaited with keen interest by all concerned in the sanitary administration of our great dependency. We trust, however, that the new engineering experts will be made part and parcel of the department under the direction of the Sanitary Commissioners with the Government, and not form a sort of *imperium in imperio*, responsible only to the heads of the Department of Public Works. Up to comparatively late years, sanitation in India could hardly be said to be anything more than domestic sanitation on a large scale, and the technical questions involved fell easily within the powers of the ordinary medical graduate in sanitary science, but the growing necessity to deal with our great Indian cities on European lines has altered all this, and at the present day large sanitary engineering works are constantly in progress in every province.

The large waterworks which have been built during the last decade first brought the necessity of the entertainment of engineering specialists to the front, and most of these undertakings already possess a resident engineer, which for some years most provinces have possessed a consulting engineer in this branch, but these officials have been either municipal servants or attached to the department of public works, and hence, though practically forming an integral part of our sanitary administration, have been of it, but not in it.

Benares is already provided with a system of sewerage on modern lines, and there can be no doubt that ere long the same must be done for our other great cities. The local peculiarities of Oriental towns differ, however, so markedly from those of Europe, that experience gained in the one field, however valuable, cannot qualify a man to take up, off hand, work in the other, and it is probably owing to this that the Government is now proposing to institute a special service of sanitary engineers. Any such accession of strength should, however, be made a part of one department, working along with the medical specialists under the direction of the Sanitary Commissioner. The training of a sanitary engineer, however able he may be, does not qualify him to decide what measures will be best suited to maintain the public health, any more than that of the medical graduate in sanitation makes him a judge of the best section and gradient for a sewer, or of the relative merits of different patterns of sluice valve.

The medical sanitarian, in fact, knows best what should be done, while his engineering colleague alone understands how to do it. The question of what to do remains, however, the consideration of primary importance, and unless this very obvious fact is kept well in mind by the Government there will be a grave risk of the Sanitary Commissioner being reduced to a cypher in the decision as to what measures should be adopted. To give a possible instance: The relative merits of septic tanks as compared with intermittent ærobic filtration, and their relative applicability to local needs, are questions for the medical expert; their construction, when decided upon, that of the engineer; but unless the medical element be given the key of the position, it may be taken as certain that the man best qualified to judge as to the health requirements of a locality will have but little voice in determining what plan should be selected.

The provincial sanitary committees were, and it is believed still are, composed of the head of the Provincial Department of Public Works, the Consulting Sanitary Engineer, the Inspector-general of Civil Hospitals, and the Provincial Sanitary Commissioner, a constitution which, it will be observed, in case of a difference of opinion between the engineering and medical elements, leaves the parties equally divided, and hence throws the ultimate decision on the executive authorities, who cannot be expected to understand much of the relative merits of either point of view.

Now, in practice those who have sat on such Committees know too well that it is extremely difficult for the medical members to carry into effect their views on the proposals brought before the Committee. A new meat market, for example, is projected for some town, and the engineers bring before the Committee plans, the preparation of which represents much trouble and expense, but which are obviously ill suited to the purpose, from the public health point of view, owing to ventilation being insufficiently provided for. The carrying out of the medical members' modification would involve the preparation of com-

pletely new plans, and probably spoil the architectural effect of the building. Assuming that the medical members stand to their guns, an attitude which involves much trouble and correspondence, the decision necessarily rests with the Lieutenant-Governor, who, as likely as not, argues that a sanitary engineer ought to know as well how to plan a meat market as any "doctor," and the result is at best the concession of a few utterly inadequate additional openings, and a building quite unsuited for the purpose for which it is designed, while the medical members are condemned as being impracticable and "wanting in tact." While, therefore, welcoming the proposed accession to the strength of our Indian sanitary forces, we trust that Government will take care that the engineering element shall be the helper, but not the master, of the Medical Sanitary Authorities.

LEPROSY IN COLOMBIA.

THE report that there were 30,000 lepers in a population of 4,000,000 in the Republic of Colombia, South America, is denied by the Colombian officials. The Consul General in London states there are but 5,000 lepers in a population of 5,000,000.

The leper settlements in Colombia are at Agua de Dios, Cano del Loro, and Contratacion; the last-named is to be removed to Capitia at an early date.

The Colombian Government are taking steps to place these three settlements in a thoroughly hygienic state.

Miscellaneous.

FIGHTING TROPICAL DISEASE.

A HANDSOME DONATION TO THE LIVERPOOL SCHOOL OF TROPICAL MEDICINE FROM H.M. THE KING OF THE BELGIANS.

HOME SCOURGES PREVENTABLE.

A COMPLIMENTARY luncheon to Professor Ronald Ross, C.B., Professor R. Boyce, and Dr. J. L. Todd (in recognition of the decoration recently conferred on them by His Majesty the King of the Belgians for services in research into tropical diseases at the Liverpool School of Tropical Medicine), was given by the Lord Mayor of Liverpool (Alderman Joseph Ball) on October 1st, at the Town Hall, Liverpool. The following was the list of acceptances: Lord Mountmorres, Sir Alfred L. Jones, the Lord Provost of Edinburgh (Sir Robert Cranston), Sir James Barr, Mr. George Brocklehurst, Mr. W. Adamson, Alderman F. Smith, Mr. T. F. Harrison, Professor Moore, Mr. A. R. Marshall, Mr. W. Roberts, Dr. Evans, Colonel Frank Walker, Alderman E. Walker, Mr. Henry Jones, Dr. Nisbet, Alderman W. Hall Jowett, Mr. W. J. Bellis (Chairman of the Junior Reform Club), Mr. W. Muirhead (Chairman of the Junior Conservative Club), Mr. T. H. Barker, the Belgian Consul (Mons. E. Seve), Mr. C. Livingston, Dr. Caton, Mr. F. C. Danson, Mr. R. W. Leyland, Alderman M. Hyslop Maxwell, Mr. A. H. Milne, Colonel Dobson, Mr. Ellis Edwards, Alderman C. H. Giles, Mr. A. Lawrence, and Mr. J. Gaffney. The Police Band played during the reception and repast.

After the loyal toasts had been duly honoured, the Lord Mayor, in proposing "Our Guests," said he had asked these three distinguished gentlemen to accept the hospitality of the Town Hall because he considered that honour should be paid to whom honour was due. Under the auspices of the Liverpool School of Tropical Medicine, Professor Ross, Professor Boyce, and Dr. Todd had undertaken the investigation of sleeping sickness, towards which work the King of the Belgians contributed a sum equal to £4,000 English. Having been satisfied with the work which was so effectively done and of such great value, His Majesty conferred upon these gentlemen a decoration of a personal character. He was sorry that Professor Boyce was not present. He had hoped to have attended this complimentary luncheon, but his doctor forbade him to travel from Harrogate. Proceeding, he remarked that Professor Ross had just received the honorary degree of Doctor of Law at Aberdeen University, while in 1902 he was awarded the Nobel prize for his discoveries in malaria. Dr. J. L. Todd was a medical graduate of M'Gill University, Canada. He had participated in several very important expeditions of the Liverpool School of Tropical Medicine, and had been identified with the late Dr. Dutton in carrying out the extensive study of sleeping sickness. Professor Boyce was the Dean of the Tropical School, which owed its inception to Sir Alfred Jones' and Professor Boyce's energy. As Chairman of the School of Tropical Medicine, Sir Alfred Jones had brought to bear great business capacity, much foresight, unbounded generosity, and an amount of enthusiasm, without which the work would have lacked much of its force. The Tropical School had only been in operation since 1899, and by 1905 £48,200 had been collected. Never was money more profitably spent than this £48,000. Sixteen expeditions had been sent out to tropical and sub-tropical countries. About 900 cases of various tropical diseases had been treated at a special ward in the Royal Southern Hospital, Liverpool, and he was glad that they had the Chairman of that hospital (Mr. Wm. Anderson) with them that day. Moreover, they were honoured with the presence of the Belgian Consul, and through him he begged to assure His Majesty the King of the Belgians of Liverpool's warm appreciation of his gracious act.

Sir Alfred Jones, in cordially seconding the toast, read a translation of a letter from the Secretary-General, Congo Free State, dated Brussels, September 28th. It stated: "You made reference to the fact that if his Majesty Leopold II. would consent to make an annual subscription of £1,000 for a period of five years, the Liverpool School of Tropical Medicine would be relieved of pecuniary difficulties. I have the honour to inform you that his Majesty the Sovereign King, responding to this appeal, has authorised me to place at your disposal a sum of £1,000. We hope that this subscription will not be the last which might be made to the institute."

A letter was read from Professor Boyce, who said the honour to himself and his colleagues was really paid to the Liverpool School of Tropical Medicine.

Professor Ross, in response, remarked that he had been previously honoured at the Town Hall during the Lord Mayoralty of Mr. W. Watson Rutherford, M.P. He should not only like to see all tropical diseases banished, but likewise all preventable diseases at home, such as measles, scarlet fever, and chicken pox. He believed that by the discovery of the causes such diseases could all be wiped out.

Dr. Todd, likewise acknowledging the toast, drew attention to the proposed memorial to Dr. Dutton, who had left a glorious example of self-sacrifice.

The Belgian Consul expressed, in the name of King Leopold and his fellow-countrymen, their congratulations on the success of the Liverpool School of Tropical Medicine, which was known all over the world.

The Lord Mayor, again rising, said: I should not like to part without asking you to drink the health of the Lord Provost of Edinburgh (Sir Robert Cranston, K.C.V.O.). His lordship has come to Liverpool to attend a church function in Everton, and I embraced the opportunity of inviting him to join us at luncheon to-day. If I mistake not, he will have been very much interested in all that has passed to-day. I venture to hope that the seed thus sown in his mind will ripen and bear fruit. We are not using Sir Robert as a medium for collecting money—the thought farthest in our minds—but we should like him, when he gets an opportunity in his own city, in which he is so respected and has so much power, to sing the praises of the Liverpool School, which is doing so much to reduce the diseases brought about by malaria. The more we can make known this fact the better it is for the world. We are not working on our own account, but for the good of humanity—helpless humanity. Gentlemen, the health of the Lord Provost of Edinburgh.

The Lord Provost, in reply, said Scotland was a poor country, but it would appreciate what the Lord Mayor had said. He agreed that municipalities should try to discover the causes and to eradicate preventable disease.

Sir James Barr gave "The Lord Mayor," and with his lordship's response the pleasant proceedings were concluded.

The Lord Mayor directed that the following telegram should be sent to King Leopold: "Grand Marichal de la Gour, Brussels.—Please convey to his Majesty the King of the Belgians the very hearty thanks of myself and the School of Tropical Medicine for the decorations conferred upon Professors Ross, Boyce, and Todd, and our warm appreciation of his Majesty's generous donation towards the noble work of stamping out disease. Am now giving luncheon party in honour of the three professors, and we present our respectful thanks to his Majesty.—From the Lord Mayor of Liverpool."—*Liverpool Post*, October 2nd, 1906.

Reviews.

THE PRINCIPLES OF TREATMENT AND THEIR APPLICATION TO PRACTICAL MEDICINE. By J. Mitchell Bruce, M.A., M.D., LL.D., F.R.C.P. Third Edition. Edinburgh and London: Young J. Pentland, 1905. (Demy 8vo, pp. 614.)

We have only had a few books in medical literature during the past century which can be said to approach the grade of classical literature. Symes' Principles of Surgery, Huxley's Physiology, and Watson's Medicine, are, perhaps, the most outstanding books of the kind, and were we to link the earlier editions of Druitt's Surgery, and Erichsen's Science and Art of Surgery with these, the list may be said to be completed. The Principles of Treatment, by Dr. Mitchell Bruce, revives the hope that the writers of to-day can approach these classical writers, and even surpass several. The Principles of Treatment, by Dr. Bruce, may legitimately be classed along with Symes' Principles, and higher praise cannot be bestowed upon any medical work. It is, moreover, encouraging that the book has reached a third edition, as it proves that medical men, in the multiplicity of books and periodicals, have not altogether lost taste for the classical in medicine. Every medical man who has a regard for the ideal in medicine and in the treatment of disease, has Bruce's Principles of Treatment on his shelf.

Correspondence.

THE IMMUNITY OF NEGROES TO VARIOUS FORMS OF CANCERS.

To the Editors of the JOURNAL OF TROPICAL MEDICINE.

GENTLEMEN,—Permit me to ask, through your pages, whether any of your readers have observed epithelioma of skin or rodent ulcer in negroes? During twelve years' practice I have only once seen this disease in one negro, and in this case the patient is an albino. Unfortunately, I have not yet persuaded him to allow its removal, though he promises to. My father, Dr. W. J. Branch, after forty years in the West Indies, has admitted to me that he cannot recall a single instance of this cancer in a black person. Cauliflower cancer of the cervix is the only epithelioma that in my experience affects West Indian negroes, and I have practised in six islands and have some acquaintance with several others. Among the poor whites, rodent ulcer and epithelioma of the lip are decidedly common.

If this exemption of the black skin from malignant disease is borne out by the experience of others, it is curious that more attention has not been directed to the phenomenon.

Yours, &c.,

C. W. BRANCH, M.B., C.M.

St. Vincent, British West Indies.
September 28th, 1906.

SCHAUDINN MEMORIAL.

THE FRITZ SCHAUDINN MEDAL.

IN memory of Fritz Schaudinn, the famous Protozöologist, who enriched our knowledge by many discoveries, one of which was the cause of syphilis, there

will be presented, on the anniversary of his all too early death, a medal to the author of the most remarkable work on Microbiology. At present it is intended that the medal shall be given once every two years, and the presentation will take place through the medium of the Institut für Schiffs-und Tropenkrankeiten at Hamburg, on the staff of which Schaudinn worked before his death. It was ever his desire that protozöology should be considered to be, like bacteriology, a part of microbiology, in any department of which work worthy of the medal may be done. The necessary funds are already guaranteed, and care will be taken to secure the co-operation of scientists of all lands in the decision as to the worker best deserving the medal.

[We are glad to know that Schaudinn and his brilliant work is to be commemorated in a suitable fashion. We are obliged to the authorities of the Seemans Krankenhaus und Institut für Schiffs-und Tropenkrankheiten, Hamburg, for the above notice.—Ed. *J.T.M.*]

Dear Sir,—As you may perhaps be aware a movement has recently been set on foot in England to co-operate with Germany in forming a Memorial Fund for the wife and children of the late Fritz Schaudinn, of Hamburg. The list of the achievements of this eminent investigator is a long and distinguished one, and includes not only discoveries of the highest theoretical importance, but also many of practical application to disease as in the case of his well-known researches on amæbic dysentery and malaria. The last, and perhaps the chief, of his achievements, viz., the discovery of the micro-organism of syphilis, was made just before his death, and is still fresh in the public mind. The enclosed circulars indicate sufficiently, I think, the need for the formation of such a Memorial Fund.

Since the present state of international feeling renders it desirable that this British tribute of admiration to a great German should be as weighty as possible I have ventured to send you a copy of the appeal. I need scarcely add that the addition of your name to the Committee will be a valuable accession to its strength.

I am, &c.,
W. S. Perrin.
(*Hon. Sec. of the Committee.*)

The Museums, Cambridge.
October 12*th*, 1906.

SCHAUDINN MEMORIAL

[*Translation.*]

Dear Sir,—As I already informed you our Schaudinn was released from his sufferings on Friday morning last. His condition from the moment he came under medical treatment not only gave occasion for the gravest apprehensions, but was regarded as almost hopeless by the physician, ... For weeks we lived between hope and fear without suspecting how serious matters were with him. Now he is taken away from us. What we have lost in him you know. The distress is so much greater in that we have no adequate substitute for him. Whether Protozoology, which had begun under his guidance to develop so brilliantly, will become without him what he promised to create for it, the future will show. But the blow has struck those he has left behind hardest of all his poor young wife, who expects within a few weeks the birth of a third child, and his two little children, a girl and a boy. They have all lost in their father their only support. The state of Hamburg of course pays a widow and orphan pension and will assess this as highly as the legal definitions in any way permit. In spite of this it can only be a modest one, since Schaudinn died so young, little more than £100 for the widow and £25 for each of the children. It will thus be of value to render private assistance, *i.e.*, to collect together some kind of memorial fund. An appeal, which it has been decided to publish, will address itself chiefly to the medical profession, and we are reckoning upon the dermatologists taking a prominent part. Among these Neisser, and others, have already promised their assistance. In addition a special grant on the part of the Prussian and Imperial authorities is hoped for. I should, however, think that the interest in Schaudinn abroad will not end with his life, but that people will gladly give proof of their high esteem for the dead to his family, which he has left behind in grief and necessity, by taking part in the work of love.

I therefore approach you with the request to open among your countrymen the matter, which now occupies all the friends of the dead, and which we can scarcely bring to the desired end through our power. I intend to apply to my friend Minot in America, and Blanchard in France, with the same request. In carrying out the plan I should much prefer to personally remain completely in the background; naturally, however, I place myself completely at your disposal with respect to any further information that may be desired.

Giessen, J. W. Spengel.
June 28*th*, 1906.

Dear Sir,—The enclosed letter has been received by Mr. Sedgwick from Professor Spengel, of Giessen.

It is proposed to co-operate in the movement which has been set on foot in Germany by forming a Committee of scientific men interested in Dr. Schaudinn's work. A list of the gentlemen who have already signified their approval of this scheme and have consented to join the Committee is now sent you. I have the honour to ask you if you will allow your name to be included in their number.

Subscriptions may be paid to Mr. Adam Sedgwick (at the above address), Treasurer of the Fund, or direct to the Schaudinn Memorial Fund at Messrs. Barclay and Co.'s Bank, Cambridge.

I am, &c.,
W. S. Perrin,
Hon. Sec. of the Committee.

New Museums, Cambridge,
July 14*th*, 1906.

Committee.—Professor Clifford Allbutt, F.R.S., Sir Michael Foster, K.C.B., F.R.S., Mr. Jonathan Hutchinson, F.R.S., Professor E. Ray Lankester, F.R.S., Sir Patrick Manson, K.C.M.G., F.R.S., Professor William Osler, F.R.S., Mr. John Tweedy, President of the Royal College of Surgeons, Professor Sims Woodhead, F.R.S.E.

The following subscriptions have been received or promised:—

	£	*s.*	*d.*
The Right Hon. Lord Lister ...	20	0	0
Mr. A. Sedgwick	1	0	0
Mr. J. J. Lister...	5	0	0
Professor Sims Woodhead ...	5	0	0
Dr. J. Hutchinson	5	5	0
Mr. A. E. Shipley	1	1	0
Professor W. Osler	5	5	0
Professor T. Clifford Allbutt ...	2	2	0

[It is to be hoped that medical men in practice in the Tropics, in view of the great advance in our knowledge of tropical diseases due to Schaudinn, will subscribe to the Schaudinn fund.—Ed. *J.T.M.*]

Books and Papers Received.

"The Prescriber."

We are favoured with the first number of a new monthly publication devoted to the pharmacy of the newer remedies, termed *The Prescriber*. The periodical is edited by Thomas Stephenson, F.C.S., Ph.C. A journal specially devoted to prescriptions and prescribing would be popular with medical men. We will await the development of the journal with interest, and hope that prescriptions and prescribing, as well as pharmacology, will find a place in future numbers. The journal is published in Edinburgh.

Notes and News.

Mr. Andrew Carnegie has given £10,000 to build a library for the University of St. Andrew's, of which University he is Lord Rector. Dundee University College also benefits by the sum of £12,500 given by the same generous donor for the purposes of a public laboratory.

Brussels School of Tropical Medicine.—King Leopold opened the School of Tropical Medicine at Brussels, on October 13th. The School was founded by King Leopold, who has for many years appreciated the importance of the investigation of diseases in his tropical possessions and colonies. The Director of the School is Dr. van Campenhout, formerly the Superintendent of the Colonial Sanatorium at Watermael. Although the investigation of sleeping sickness will take a prominent place in the immediate investigations to be carried on at the School, instruction will be provided in all departments of tropical medicine. The links of sympathy and practical interest which already exist between the schools of tropical medicine in London, Liverpool, Paris, and Hamburg, will extend to the new school in Brussels, and it is to be hoped the several schools will still keep touch with each other in the future as they have done in the past.

Sir Frederick Treves' interesting book, "The other Side of the Lantern," published by Cassell and Co., London, is re-issued in a "popular" edition. "The other Side of the Lantern" is a graphic and personal account of what the writer saw and noted in his journey round the world. It is written in the terse and enlivening style characteristic of all Sir Frederick Treves writes and does.

It is probable that Major Bird, C.I.E., Professor of Surgery in the Medical College, Calcutta, will be appointed Medical Officer in attendance on the Amir during His Highness's tour in India. Major Bird, it may be remembered, was highly successful at Kabul in treating injuries to the Amir's hand caused by an accident while shooting.—*Pioneer Mail*, September 14th, 1906.

In spite of some inexplicable opposition from the Rangoon Chamber of Commerce, a branch of Lady Minto's scheme for an Indian Nursing Association is to be established in Burmah, and no country stands in more urgent need of an efficient organisation of the kind.

The first report of the health officer of Rangoon is couched in a somewhat desponding vein, and it cannot be denied that the rat-killing operations have, as yet, not proved a particular success; but this is probably because the business has been taken up in a very half-hearted fashion. It stands to reason that, to be effectual, the campaign against rats should be conducted simultaneously throughout the entire town, and this does not appear to have been as yet attempted in Rangoon. Rats are notorious for their sagacity, and, it is well known, migrate at once should any considerable mortality occur among them, whether brought about by plague, poisoning, or any other cause. The result, therefore, of partial attempt is merely to spread the disease to quarters of a town that have been left untouched.

A fashionable wedding took place at Rangoon on September 6th, between Miss Linda Wilkins, daughter of the popular P.M.O., of the Secunderabad Division, and Lieut.-Colonel Menzies, Rangoon Port Defence Volunteers. The ceremony was conducted by the Right Rev. the Bishop of Rangoon.

A course of not less than four lectures on the prevention of disease will be delivered annually at all stations where British troops are quartered. Whenever practicable, the dates selected for the lectures will be between April 1st and October 31st. The lectures will be delivered by Royal Army Medical Corps Officers, who will be selected by the General Officers Commanding Divisions and Brigades, with special reference to their fitness for dealing with the subject. Attendance at the lectures will be voluntary, but General and other Officers Commanding should impress on those under them the importance of acquiring some knowledge of this subject. The first series of lectures commence this month. This is a most excellent innovation, as there cannot be the least doubt that a large proportion of sickness in India, alike among Officers and men, is entirely due to ignorance of the precautions that should be adopted by all reasonable persons in such a climate.

X-ray installations will shortly be introduced at ten central stations in India for army purposes. So far so good: as far as those quartered at these particular stations are concerned; but what about the large majority who are posted elsewhere? This means that at all other than these central stations, any case that may occur must needs await diagnosis until, in response to a proper official requisition, with an appropriate width of "margin," the apparatus is despatched to the outstation, a procedure that must often involve a delay of several days at the most critical period of a case. Although rather expensive, an X-ray apparatus is not costly enough to warrant so pitiable and misplaced an economy, and as many

private practitioners can provide themselves with one, Government can surely afford these appliances to each station, for at the present day an outfit of the sort has become one of the necessities of surgical life.

Two successful cases of treatment of snake-bite by the combined use of antivenene and the local application of permanganate, are noted in the annual report of the Sanitary Commissioner of the Central Provinces, India. In both cases a ligature had been applied immediately after the bite, and in one of them two hours elapsed before any other treatment could be adopted.

It is understood that the Government of India have appointed a Committee, consisting of Lieut.-Colonel Leslie, I.M.S., Sanitary Commissioner with the Government of India, Mr. Lionel Jacob, Secretary to Government in the Public Works Department, and Mr. D. Aikman, to draw up a scheme for the creation of a service of sanitary engineers as a separate branch of the Public Works Department. The Committee will draw up the regulations and conditions of service, &c. —*Pioneer Mail*, September 14th, 1906.

The death is announced of Captain F. A. Pilkington, I.M.S., of heart failure. The deceased officer was well known and highly esteemed in Lahore.

On November 9th, 1906, Professor Ronald Ross, F.R.S., C.B., will give an address on the subject of "Malaria in Greece," to the Medical Society of Oxford.

X-ray Burns.—In a discussion on the treatment of X-ray burns at a recent meeting of the New York Dermatological Society, as reported in the *Journal of Cutaneous Diseases*, Dr. Henry C. Piffard, Emeritus Professor of Dermatology in New York University, said that he had "obtained the most benefit in treating X-ray burns with antiphlogistine, chloride of zinc, high frequency current, and ultra violet rays."

Owing to the rapid spread of the cocaine habit in India, the Punjab Government has issued a notification under the Excise Act that cocaine, and every preparation and admixture of cocaine, are henceforth included in the definition of "intoxicating drinks." This will give the authorities the same powers of regulating the sale of the drug that they possess in the case of opium, Indian hemp or alcohol.

Some time ago it was pointed out in "Notes and News," that the Hindu population in India would probably raise objections to the killing of rats, and already one can hardly take up an Indian paper without finding allusions to this difficulty, which constitutes the greatest obstacle to the efficient carrying out of this most practical of anti-plague measures. In Nagpur, the capital of the Central Provinces, a *Guru*, or Hindu religious leader, has been preaching against the sin of killing rats, and on being asked by Mr. Dewar, the Executive civil officer, what he thought of tiger shooting, the *Guru* replied that that was not a sin, but a duty. Mr. Dewar pointed out that at present rats were destroying far more human lives than tigers had ever done; but common-sense and reason weigh so little with religious fanatics of any denomination that it may be feared that his most apposite parallel had little effect on the Guru's crusade. Accordingly, Mr. Ram Narayan, an influential native banker, proposes to provide a "rat-ruksha" or sort of pen in which the captured rats may be confined as pensioners for the natural term of their lives, the male and female animals being kept apart. To the home-staying European, all this appears too "Gilbertian" for grave consideration, but the proposal has been most gratefully received by Major Buchanan, I.M.S., who is in charge of the plague operations, and the thanks of all interested in Indian sanitation are due to Mr. Ram Narayan for a proposal which smooths the way over what bids fair to become an insuperable *impasse*. In the Punjab, on the other hand, the campaign against rats progresses steadily, and does not appear to be rousing opposition. Already nearly sixty towns have been included in the operations.

An instance of the dangers attendant on the storing of grain in hot, damp climates, comes to us from Bangalore, where a serious outbreak of diarrhœa, which raised suspicions of the presence of cholera in the town, was traced to this cause. The stale corn was disposed of by mixing with sound grain in sufficient proportion to mask the musty odour of the decomposed article.

A professor of Biology is to be added to the staff of the Lahore Government College.

We learn that Lieutenant F. H. Stewart, I.M.S., who recently applied to Government for the post of Surgeon Naturalist, Marine Survey of India, has been posted to Gyantze, Thibet! The fact of the would-be deep sea fisher being sent to sit on the top of mountains 12,000 to 15,000 feet high needs no comment.—*Pioneer Mail*, October 5th.

The contributions to Lady Minto's endowment fund for European-trained nurses now amounts to over £8,000.

The *Pioneer Mail* of October 5th includes a useful review "by a specialist" of the measures that have hitherto been adopted for the suppression of plague, in light of our more recent knowledge as to the mechanism of its conveyance. He shows how the failure of protective cordons was inevitable, evacuation merely a palliative, and why disinfection, in the ordinary sense of the term, is worse than useless. Inoculation he regards as needless, in view of the fact that plague may now be regarded as though *the most troublesome of all our epidemics, it is the most easily preventable*. While in no way minimising the obstacles of native prejudices against rat-killing, he believes that the opposition will die down "as soon as the people understand that plague is primarily a rat disease." In one point we would, however, wish to set our contemporary correspondent right in a matter of history, when he says:— "Men were employed to disinfect houses, and a con-

siderable number of those who were employed on this work were attacked by plague. Boots and putties were provided for these workers, and with good results, but it probably never occurred to any one that the boots and putties produced their good effect by preventing the workers from being bitten by rat fleas." Now, as a matter of fact, ammunition boots with pyjamas tucked into them at the ankle, were ordered to be worn by the men of the disinfecting gangs, by the Sanitary Commissioner of the North West Province and Oudh in 1899, because the holder of the appointment at that date held a firm belief that some insect such as the bed-bug or the flea would ultimately be proved to be the actual carriers of the disease, in spite of the discredit that then was thrown on the idea by bacteriologists, and he further directed that the boots as well as the legs and arms of the men engaged in the work should be kept greased with carbolic oil on account of the well-known aversion of fleas and other insects to greasy and strongly-smelling substances. The theory, it must be remembered, is a fairly old one, and although the triumph of the truth is but so recent a matter, the idea had even then already occurred to Lieutenant (now Captain) Glen Liston, although he did not publish any note on the subject till long afterwards. The certainty of our knowledge, and the conviction that, given intelligent co-operation on the part of the populace, plague is an easily controllable disease, is, however, a pleasant contrast to the groping in the dark of those days; for even those of us who most strongly held that plague must be conveyed by the agency of biting insects, had nothing but analogy to go on. The suggestion of using boots, &c., was, however, as a matter of fact, based on the idea that either fleas or bed bugs might very possibly be concerned in the matter, as it was felt that the circumstances of the case rather put our old friend the mosquito out of court, because were those insects capable of conveying the disease, few would be likely to escape.

A SPECIAL correspondent of the *Times of India* who has been visiting Poona to investigate the causes of the terrible exacerbation of plague in that city, draws a gruesome picture of the insanitary conditions subsisting in the poorer parts of the town. It is obvious that rat-killing operations can stand but little chance of success in such a honeycomb of dark, overcrowded cells as he pictures the homes of the people to be.

Personal Notes.

INDIAN MEDICAL SERVICES.

Arrivals Reported in London.—Lieutenant-Colonel E. W. Reilly, Captain T. G. N. Stokes, Major F. R. Ozzard, Major W. A. White, Major C. L. Williams, Captain F. H. G. Hutchinson.

Extensions of Leave.—Lieutenant-Colonel J. W. Poynder, 2 m. 21 d. leave, medical certificate; Major C. Duer, 3 m. furlough; Captain N. R. Rainer, study leave, May 1st to June 15th, 1906; Captain S. Anderson, study leave, April 11th to August 31st, 1906; Captain A. Miller, 6 m. furlough; Major S. A. Harris, 3 m. medical certificate; Captain S. Evans, M.B., 6 m. medical certificate; Captain H. R. Brown, 7 d.; Major T. W. Irvine, special leave commuted to furlough P.A. and extended 2 m. 8 d.; Major E. Wilkinson, study leave, May 1st to July 31st, 1906; Captain R. Brown, 14 d.; Captain R. M. Carter, 2 m. Captain J. H. Hugo, furlough to March 6th, 1907; Captain N. R. J. Ranier, study leave, June 16th to October 1st, 1906: Major W. H. W. Elliot, D.S.O., 27 days.

Permitted to Return to Duty.—Major J. Morwood, Major T. W. Irvine, Captain R. M. Dalziel, Major A. Street, Colonel H. Hamilton, C.B., M.D., Lieutenant-Colonel C. J. Starkies, Lieutenant-Colonel M. A. T. Collie, Captain L. J. M. Deas, Captain F. D. Browne, Lieutenant-Colonel R. H. Cama, Captain D. G. R. S. Baker, Captain A. E. J. Lister, Major P. J. Lumsden, Lieutenant-Colonel J. S. Daly, Major W. H. W. Elliot.

Trooping.—The following officers of the R.A.M.C., embarked on the *Rewa* for India on the 19th ult.: Colonel P. M. Ellis, Lieutenant-Colonel R. L. R. Macleod, Lieutenant-Colonel D. M. O'Callaghan, Captain A. W. Hooper.

Postings.

On transfer from Ferozepore, Major E. V. Hugo, I.M.S., is appointed to officiate as Civil Surgeon of Lahore, Professor of Midwifery and Forensic Medicine, Lahore Medical College, and Medical Officer in charge of the Medical College, Lahore, relieving Lieutenant-Colonel H. Hendley, I.M.S., proceeding on leave.

Captain Paton, services replaced under Sanitary Commissioner with Government of India.

Captain W. M. Pearson officiates as Deputy Sanitary Commissioner, 2nd Circle, United Provinces.

Captain W. H. Cazaly acts as Deputy Sanitary Commissioner, Southern Registration District, Bombay.

Captain H. Crosbie to additional charge of current duties as H.M. Consul, Kermanshah.

Major A. L. Duke, to additional charge of current duties as Political Agent, Bikanir.

Major R. J. Macnamara, services placed at disposal Sail Department, Government of Madras.

Colonel J. McCloghry is transferred as P.M.O. from Quetta, to Abbotabad.

Colonel H. K. McKao, C.I.E., from the Presidency and Assam Brigades to the Meerut Division.

Hon. Lieutenant L. J. O'Reilly, I.S.M.D., to be Civil Surgeon, Etah.

Major W. Vost is transferred from Gorakpur to Muttra, as Civil Surgeon.

Major D. M. Moir, Professor Medical College, Calcutta, is appointed to the Managing Committee of the Zoological Gardens, Calcutta.

Captain W. O'S. Murphy to the charge of the Observation Camp for Pilgrims, Perim, Dr. J. H. Walsh, Uncovenanted Medical Service, acting in his place as Special Health Officer, Kurachi.

On return from leave, Surgeon-General W. R. Brown, I.M.S., will become Surgeon-General with the Government of Madras, and Colonel P. Benson, I.M.S., who has been officiating, will go as Principal Medical Officer to the 6th (Poona) Division.

Captain D. Munro, to the Medical Charge, 11th Lancers.

Major F. R. Ozzard, to the Medical Charge, 7th Rajputs.

Captain A. Lister, to the Medical Charge, 19th Punjabis.

Captain N. W. Macworth, to the Medical Charge, 41st Dogras.

Captain R. M. Barron, to the 54th Sikhs.

Captain R. F. Bird is placed on Plague duty.

On return from leave Major S. K. Close becomes Civil Surgeon of Shahjahanpur, relieving Major J. G. Humbert, who goes to Farrukhabad.

Hon. Captain E. P. Clements, I.S.M.D., to be Civil Surgeon, Hardoi.

Captain E. L. Perry, officiates as Civil Surgeon, Dera Ghazi Khan.

Leave.

Colonel H. Barrow, R.A.M.C., for 6 m.
Lieutenant W. Brayne, 8 m. combined leave.
Captain D. N. Anderson, 6 m. combined leave.
Captain J. C. Kunhardt, 8 m. furlough.
Captain J. C. Robertson, 2 y. combined leave.
Captain F. H. Hutchinson, 1 y. 7 m. combined leave.
Captain F. Wall, 6 m., medical certificate.

Retirements.

The following Senior Assistant Surgeons, Bengal, are permitted to retire: Honorary Captains Brown, Bailey, and Hogan.

Lieutenant R. Cobb is permitted to retire.

Captain L. Gundall is transferred to the temporary half-pay list.

Promotions.

Captains to be Majors, July 28th, 1906.—Thomas Arthur Granger, M.B., Harold John Kinnahan Bamfield, John Wemyss Grant, M.B., Arthur Henry Moorhoad, M.B., William Davey Hayward, M.B., William Elmsley Scott-Moncrieff, M.D.

Lieutenants to be Captains, August 31st, 1906.—Robert Kelsall, M.B., John Hay Burgess, M.B., F.R.C.S., Charles Hildred Brodribb, M.B., John McCallum Anderson Macmillan, M.B., Clifford Allchin Gill, William Edward James Tuohy, Terence Francis Owens, Richard Francis Steel, M.B., George Francis Innes Harkness, Arthur Charles Ingram, M.D., Gordon William Maconachie, M.B., Ernest William Charles Bradfield, M.B., Alexander William Montgomery Harvey, M.B., Charles Isherwood Brierley, John Brown Dalziel Hunter, M.B., Edward Temple Harris.

Robert Joseph Macnamara, M.D., Herbert Wilson Pilgrim, M.B., F.R.C.S., Francis Wyville-Thomson, M.B., Edwin Harold Brown, M.D., F.R.C.S.E., Charles Norman Bensley, Selby Herriot Henderson, M.B., Blenman Buhos Grayfoot, M.D., David Wilson Scotland, M.B., Charles Robert Mortimer Green, F.R.C.S., Richard Henderson Castor, Thomas Edward Dyson, M.B., Edward Christian, Hare Frank Cecil Clarkson, John Gregory Jordan, M.B., Herbert Mackinlay Morris, Allan Rupert Postance Russell, James Morwood, M.D., Frederick George Maidment, Edmund Alexander William Hall, M.B.—September 30th, 1906.

R.A.M.C.

On arrival from England, Colonel P. M. Ellis becomes P.M.O. Quetta Division and Colonel J. G. Harwood, P.M.O., Presidency and Assam Brigades.

Colonial Medical Service.

Cyril E. Thwaites, L.R.C.P., M.R.C.S., has been appointed Civil Assistant Resident in Northern Nigeria.

Dr. F. G. Hopkins, Senior Medical Officer of Southern Nigeria, is acting as Principal Medical Officer during the absence on leave of Dr. H. Strachan, C.M.G.

Recent and Current Literature.

A tabulated list of recent publications and articles bearing on tropical diseases is given below. To readers interested in any branch of tropical literature mentioned in these lists the Editors of the Journal of Tropical Medicine *will be pleased, when possible, to send, on application, the medical journals in which the articles appear.*

"Lancet," September 29, 1906.

(I.) Two Cases of Hepatic Abscess Treated by the Transpleural Operation.

Taylor, H., describes two cases of tropical abscess of the liver, treated by incision, removal of part of a rib, opening the pleural cavity, cutting the diaphragm, and on reaching the liver stitching the liver to the adjacent parts. In one patient, as usual, "very shallow, and interrupted respiration supervened on the admission of air to the pleural sac and patient became very cyanotic." In the same patient, "while the wound was being gently syringed out with 1 in 40 carbolic lotion, the patient suddenly complained of great pain in the epigastrium, became pallid, broke out into a profuse perspiration and vomited." Syringing liver abscesses has been frequently condemned, and Dr. Taylor's case adds another warning against the procedure. Dr. Taylor advocates the transpleural operation and condemns the use of the trocar and cannula, indulging, as usual, in wholesale abuse of the method, stating that: "I venture to think that such stabs in the dark, or at least into an obscurity, are out of place," &c., &c. It will be seen that over-heroic operations for hepatic abscess by transthoracic and transperitoneal methods are still in vogue.

(II.) Endemic Hæmaturia.

Stock, Capt. Philip G. This is an account, from the epidemological point of view, of an outbreak of bilharzosis among the men of the 8th Hussars, at Pretoria, in 1902, in which forty-three men were attacked. The author tried to repeat Sonsino's observations as to the existence of an intermediate host, in the shape of some species of mollusc, in which the parasite passes through a *redia* stage, but failed to obtain any confirmation of this view. He accordingly strongly favours the idea that the embryos pass directly to the human host, by the agency of water, either by drinking or by bathing, and argues that the former is the more probable mechanism of infection, as some cases had occurred who had not bathed, and that a certain amount of water always enters the mouth or nostrils when bathing.

He shows that the "period of incubation," *i.e.*, the interval between infection and the appearance of symptoms, varies from one to two months, the movements of the troops giving an excellent opportunity of forming an opinion on this point. As to treatment, he makes the interesting suggestion of the administration of a toxin in the form of Wright's serum, basing his proposal on the disappearance of symptoms in two cases which contracted typhoid and in another of dysentery.

(III.) A Case of Ainhum.

Alexander, D. M., and Donaldson, R., describe a typical case of ainhum. Patient, 44, born in Port Antonio, Jamaica, went to sea at 14. Developed hypertrophy of little right toe and a subsequent narrowing behind. The part was amputated through the narrow neck, which proved to be of fibrous tissue and did not bleed when cut. The cause was not determined.

(IV.) The Study of a Case of Plague.

Cleland, Burton J., states that the lengthy incubation noted in plague is due to the fact that living plague bacilli probably liberate few, or no, toxic bodies; it is only when owing to overcrowding of a gland bringing about loss of food supply, or as the result of anti-microbic bodies when the bacilli die, that their endocellular toxins are liberated and local and systemic reaction follow in proportion to the dose. In other words, the presence of living plague germ infection belongs to the period usually named the incubation period, and because the living bacilli are not toxic, and it takes some days before the bacilli are killed and their toxins are set free. Dr. Cleland sums up the argument when he states: "The onset of signs and symptoms in plague is the first indication of commencing recovery from the disease." This statement bears out that which was enunciated by Drs. Hunter and Simpson from observations made in Hong Kong. The development of the bubo is a late phenomenon of plague; gastro-intestinal symptoms (Hunter and Simpson) precede its appearance, and, in fact, all evidences of fever. In Dr. Cleland's case also, diarrhœa was one of the first signs of infection and preceded all others by three days. This theory, which is now being widely received, explains why there is so seldom any local reaction and as rarely a lymphangitis in plague, compared with other infections, say, by streptococci, and why one set of glands are, as a rule, infected, and supports also the skin inoculation theory of plague.

"Bulletin de l'Institut Pasteur," T. iv., Nos. 17 and 18.

Anti-Cholera Inoculations in India.

Haffkine, Prof., gives an interesting *résumé* of his work on this subject extending over many years, and comes to the conclusion that although the case incidence among the vaccinated is only about a tenth of that obtaining among

the unvaccinated, the mortality among those actually attacked differs but little.

The protective effect of the vaccine commences at once and increases rapidly for the first four days after the operation, and lasts about fourteen months: after which its effects diminish rapidly and probably disappear completely.

These facts are of great interest in forecasting the chances of success of anti-typhoid inoculation, but can hardly be said to retain much interest in connection with the practical question of combating cholera, as Prof. Hankin's, of Agra, discovery of the use of permanganate of potassium for the disinfection of wells, has made cholera an easily controllable disease wherever the suspicious prejudices of the Indian native do not prevent the proper carrying out of the measure; and wherever this is the case it may be taken as certain that anti-choleraic injections will be even more stoutly resisted.

It must be remembered that these vaccinations are no light matter, and so much is this the case that in one instance in the abstracter's experience, the men of the Shropshire regiment who had had personal experience of the operation; through writhing in the agonies of cholera in a terrible outbreak at Sitapur, absolutely refused to submit to ordinary anodine hypodermic injections, because they suspected that the medical officers intended to repeat the anti-choleraic vaccinations that had been conducted in the regiment a few months previously.

DISTRIBUTION AND SYMPTOMOLOGY OF SURRA IN COCHIN CHINA.

Brau, St. Sernin, and Mutin Boudet confirm the existence of surra in Saigon, already suspected by Blin and Chaptal, but regard the occurrence as merely sporadic in mules and horses from Annam and Cape St. Jacques. They distinguish two forms—the "dry" and the œdematous—of the disease, and found that the presence of the parasites in the blood was intermittent. Inoculated dogs died in about fourteen days, after a three days' incubation. They tried treatment with mercuric methylarseniate dissolved in K. I. with encouraging results.

THE NEW ROUTE OF CUTANEOUS PENETRATION OF LARVAL ANKYLOSTOMES.

Schüffner, W.—Regarding infection by penetration of the skin as definitely established, the author attempts to define the importance of this route of infection as compared with that through the intestinal canal.

Schüffner is working in Sumatra, where ankylostomiasis is extremely common, but he nevertheless found considerable difficulties in obtaining cultures of the larvæ, and believes that this is due to the presence in the excrements of other rival organisms which may crowd out the young Ankylostomes. In his particular case the hostile and victorious organisms were *Strongylus stercoralis* and the larvæ of a fly, besides which he found it necessary to check the development of infusoria by the addition of 2 to 3 drops of a 10 per cent. solution of quinine. He specially studied the onset of cutaneous infection and finds that a few drops of a rich culture placed on the arm, produces, in half an hour, intense itching, and the subsequent formation of a pustule, but his sections of skin so infected, though they clearly demonstrated the fact of penetration, failed to confirm Loos' observations as to the hair follicles being selected by the larvæ as a point of entry. The neighbouring tissues were markedly infiltrated with eosinophyl leucocytes.

He notes that the larvæ disperse very rapidly in water, and hence concludes that infection must usually be by isolated individuals, under which circumstances the local irritation is far less than that of a mosquito bite, and no pustule forms, so that the occurrence would usually pass unnoticed. He further discusses the various cutaneous lesions that have been described, and in particular "ground itch," and comes to the conclusion that none of them bear any relation to the penetration of the ankylostomes.

In making these observations, Schüffner overlooks the undoubted fact that infection by the agency of water is probably a very rare occurrence, as the larvæ require fæcal matter for their nutrition, and die out very quickly in water unless it be grossly foul with excrement to such an extent that the most callous of indigenous races would neither drink of nor bathe in it. Note also Loos' observation of their habit of crawling out of water. The much fouled soil, however, in the neighbourhood of native villages usually teems with the larvæ, which must thus be constantly brought in contact with the naked feet and ankles of the inhabitants, while his negative results in the search for larvæ in these skin lesions can count for nothing as opposed to the positive results of previous investigators. No one pretends that larvæ can constantly be found in all stages of what is known as "ground itch," as the irritation and pustulation are maintained by the agency of scratching and of ordinary pyogenic organisms long after the larvæ have passed through the skin; which indeed must, in all probability, be rendered unfit to serve as a site for further penetration by the inflammatory changes set up. His explanation, however, of the capriciousness of the results of breeding experiments through the action of rival organisms is, however, of great importance, and to those who have worked practically at this question, accounts for much that has hitherto been puzzling.

PARASITE OF THE WHITE BLOOD CORPUSCLES OF PALM SQUIRRELS.

Patton, Capt. W. S., I.M.S.—In Kathiawar, some 98 per cent. of this squirrel (*Funambulus pennantii*) were found to be infested by a parasite of the mononuclear leucocytes, as many as half the corpuscles being infected. The parasite is of vermicular form, 13 to 15 microns long, by 3 to 4 microns wide, with pointed ends, and has been named by the author *Leucocytozoon funambuli*.

They are typical hæmogregarines, stain well with Romanovsky, and possess a voluminous nucleus (sometimes double), which is central in position, besides which there are a number of cytoplasmic granules.

Comparing infected animals with healthy squirrels from Madras, the former were found to present a marked excess of mononuclears, a point which the author believes may have a bearing on the etiology of leucocythæmia. The parasites are very numerous in the spleen and may be readily found in the liver and kidneys, but none of the organs showed any developmental forms. The only external parasite harboured by the squirrels was a louse, which proved to be a new species of the genus *Hæmatopinus*, but no evidence could be found of the louse acting as an intermediate host.

THE PENETRATION OF THE SKIN BY NEMATODE LARVÆ.

Lühe, M.—The researches of Loos on this subject appears to the author to afford an explanation of a point noted by him in 1896, in the examination of the body of a panther. The pulmonary alveola contained enormous numbers of nematode larvæ, very uniformly distributed through the organ, but without producing any obvious lesions. The other organs were free from any similar parasites except the intestine, and between the villi of the latter were young examples of *Uncinaria perniciosa* which had

caused small extravasations of blood. He now regards these facts as but another example of the migration of nematodes in the manner discovered by Loos.

"Zeitschr. fur klin. Med.," T. lviii., p. 43.

ANKYLOSTOME INFECTION *viâ.* THE SKIN.

Loos, Dr. A. Returning to the consideration of this subject, the author discusses replies to the objections that have been raised against his theory of infection and the practical considerations that result therefrom.

He first recapitulates the steps that led to his discovery—his accidental infection of himself under circumstances which rendered invasion *per os* highly improbable; the experiment on the leg of a patient an hour before amputation, and those he afterwards made on young dogs with *Ankylostoum caninum* and *duodenale*, and recalls his conclusion that the route followed by the larvæ is the venous or lymphatic system, the right heart, the lungs, trachea, œsophagus, &c. While passing through the lymphatic glands, particularly those of the axilla, large numbers of the larvæ are destroyed by phagocytes, and the stages of the process are followed out.

The symptoms produced depend largely on the number of larvæ that gain admission simultaneously. When this is serious they consist of diarrhœa, more or less general œdema, and multiple hemorrhages which he attributes, not to mechanical but to toxic action. The age of the subject greatly influences the results as the skin in the young is much more easily penetrated, and the resulting infection proportionally more serious.

Arrived in the intestine, Loos believes that the worms feed not on blood, but on the mucosa, and considers the hæmorrhage that results as accidental.

It may, however, be pointed out that in expressing this opinion Loos runs counter to the undoubted fact that the greater proportion of parasites found *post-mortem* in the intestines are swelled out like leeches, and that the contents of their intestines undoubtedly consist of blood. Moreover, when examined still living *in situ*, in a *post-mortem* conducted sufficiently early after death, the ankylostome will be found so firmly fixed to the mucous membrane that it is difficult to understand how any food other than the blood from the bite can gain access to the buccal cavity of the worm; and it may be further noted that Loeb and Smith described certain organs producing a powerfully anti-coagulant substance which would be quite useless, assuming Loos' very surprising theory on this point to be correct.

Loos does not deny infection *per os* as an occasional mode of access for the parasite, but believes that it is of very minor importance as compared with penetration of the skin, and, further, is of opinion that when the former takes place, drinking water is seldom if ever the vehicle, but that raw vegetables are more frequently concerned, though the commonest method of infection by this route is through eating with hands soiled with earth, especially in the case of miners.

He states that the larvæ die very rapidly if dried, so that unless they penetrate the skin very shortly after deposition on it, they necessarily perish; but this sensitiveness to desiccation is quite contrary to the abstractor's personal experience, and though the latter is aware that Loos explains this by the presence of other species of nematode larvæ in the cultivations used, he does not find the explanation adequate, and believes that under certain circumstances the larvæ show remarkable powers of resisting dryness, short of absolute desiccation.

A very important observation made by Loos is that larvæ that find themselves in water, crawl out of it by climbing the moist banks of the pool, and that they are thus found at all heights—on the sides of mine shafts and drivings, so that they are continually coming in contact with the hands of the miners as they feel their way along the ill-lighted passages. This migration can not, however, as Tenholt supposes, be made in search of food, as at this period of its existence the larvæ is enclosed in a capsule formed by the integuments of its last ecdysis.

The larvæ develop best at a temperature of 28° to 30° C. and still develop slowly at 15°, but the danger to miners from the disease is nevertheless always proportional to the warmth of the mine. With regard to prophylaxis, Loos, like every other practical observer who has studied the subject, comes to the conclusion that no measures other than those of an efficient conservancy can be expected to be of any real use.

"Anne. de l'Inst. Pasteur," May, 1906.

Nicolle finds that some monkeys, particularly *Macacus siniens*, show a certain amount of susceptibility to leprous inoculation, the subcutaneous method of inoculation is the only one productive of results, and the best results are obtained after successive inoculations. Inoculation according to experimental research varies from twenty-two to ninety-four days; the lesions produced are transitory, although many leprous bacilli have been shown by Nicolle within the large mononuclear leucocytes.

"British Medical Journal," October 20, 1906.

I.—NOTE ON A FILARIAL LARVÆ IN THE BLOOD OF A BLACKBIRD.

Symmers, Wm. St. Clair, found in a dead blackbird (*Terdus merula*), in his garden at Belfast, Ireland, filaria embryos in active movement in the heart blood. The larvæ resembled closely *Filaria perstans*, being without a sheath and having both extremities blunt. In size it is smaller than *perstans* and is apparently identical with the larva described by Manson in "Natives of British Guiana." The parent worm was not found in the blackbird. Avian filariasis is well known in several parts of the Tropics, but the discovery of the embryo in the British Isles, by Symmers, is of great interest, especially in regard to the geographical distribution of this parasite.

II.—MEMORANDUM ON THE OBSERVATION OF SPIROCHÆTES IN YAWS AND GRANULOMA PUDENDI.

MacLennan, Alex., in smear preparations from yaws sent from St. Vincent, West Indies, by Dr. Branch, found spirochætes similar to those of *Spirochæte pallida*. In one preparation taken from a papilloma in recurrent yaws, numerous spirochætes were observed.

In two smear preparations from *Granuloma pudendi* sent by Dr. Branch, Dr. Mackennan found spirochætes, probably *refringens*. In one smear the parasites were found much longer than the *Spirochæte pallida*, and the waving finer and closer; as many as forty waves being counted in one specimen.

III.—LARVÆ IN THE INTESTINE.

Drew, H. V., F.R.C.S., writing from Timaru, New Zealand, states that some two years ago he had as patients a mother and child suffering from a "nest of insects" similar to the condition described in the *British Medical Journal* of July 14, 1906. Mr. Drew states that the mother showed him "insects with rounded, hard, hairy backs, dark brown in colour, with black eyes, extremely repulsive looking, which ran about quickly." Santonin and purgatives brought away large numbers of these insects. Mr. Drew suggests they may be those of bot-flies, and enquires what is known concerning them.

Notices to Correspondents.

MALARIA IN GREECE.

An address delivered to the Oxford Medical Society on November 29, 1906.

By Ronald Ross, F.R.S., C.B.
Professor of Tropical Medicine, University of Liverpool.

(Professor Osler, M.D., F.R.S., in the Chair.)

Professor Osler and Gentlemen, — I consider myself extremely fortunate in being able to introduce the subject of malaria in Greece to my countrymen, through such a very appropriate avenue as the Oxford Medical Society. I was actually considering how the introduction might best be effected when I received the invitation from your Secretary to address you to-night. For where could any one who wishes to discourse of Greece do so much better than in Oxford—herself the daughter of Greece, who has borne through the ages the torch first fired in that divine country? And, since my subject is Æsculapian, what audience could I find fitter than yourselves? But my luck does not end here; for in you, Mr. President, I have chanced upon the fittest of all presidents, eminent alike in science and in the humanities, to both of which my theme appeals. Further, when I first opened my beggar's wallet for subscriptions in aid of the cause which I have to advocate to-night, it was yourself who contributed the first dole—a goodly number of solid drachmæ, in aid of Greece. The omens are therefore propitious, and if I fail it will be the fault of myself rather than of fortune.

First let the Muse explain (she is sorry that she cannot do it in hexameters) how it came that so humble an advocate as myself was selected for so great a client. Early in the year I was asked by a British Company, which owns certain large tracts of land in Greece, to go there in order to advise as to the best means of reducing the malaria which for a long time had been persecuting the Company's employees. I arrived in Greece towards the end of last May, and there, sure enough, found Andromeda in tears, awaiting the onslaught of the fell monster which was just then preparing to arise (metaphorically speaking) from his long winter sleep in order to devour her. After inspecting the latter, instead of slaying him outright, I determined, more wisely than heroically, to retire for assistance, and I am here to-night in furtherance of that intention.

Now let me begin by describing exactly my own experiences in Greece. As everyone knows, the country consists principally of a mass of mountains with small valleys between them, here and there, and many straits and inlets of the sea. In fact, the configuration is very like that of the Highlands of Scotland. The scenery does not possess the great variety of colour caused by the light and shade of the humid atmosphere of the Highlands; it is brightly but uniformly coloured. On the other hand, its comparative aridity is compensated for by a singular beauty and variety of contour, which are not excelled in the Alps or even in the Himalayas. High enough to retain for most of the months of the year an exquisite lacing of snow, the mountains, though barren and stony, make a long vista of outlines against the very lovely sky. I have never seen a sky equal to that of Greece. In the Tropics a yellow light is reflected from the burning ground upon the lower strata of the air, and only the zenith is blue; but in Greece the azure extends almost down to the horizon, except for a narrow margin of brilliant silvery or pearly light. After sunset the sky seemed to me to possess, not the deep night blue of the Tropics, but a wonderful purple tint of its own, in which the "new-bathed stars" shine with a brilliance not exceeded even in the desert. At midday, the almost tropical glare of the sun on the chalky soil is relieved by the dark shades of the plane trees and the classical cypresses, and the bright green of the vines. It has been my fortune to see many beautiful countries, but I think that Greece and Britain hold the palm.

The particular valley which I was called upon to visit was that of Lake Kopais, in Bœotia. After leaving Athens, the comfortable train winds along between Mount Pentelikon on the south and Mount Parnes on the north. Then, passing across the eastern spurs of Parnes, in full sight of the Island of Euboia and its strait on the right, it enters the valley of Thebes. Traversing this it goes through the defile of the Sphingion (where the Sphinx used to waylay travellers with her riddles) and emerges on the Kopaik Plain. This is a large area about six miles broad and twelve miles long, the long axis pointing west and east. On the east the plain is bounded by the Mountain of the Sphinx, which seems, from certain points of view, to have the shape of a woman's figure reclined along its crest. Along the whole of the south side runs the beautiful range of Helikon, the Mountain of the Muses. The birthplace of Hesiod is in one of its valleys; and near one of the summits there is the famous fountain of Hippokrene, where the winged horse, Pegasus, took flight for heaven, owing, it is said, to some annoyance from the literary critics of the day. At the western extremity of the plain rises the magnificent mass of Mount Parnassus, the Mountain of Apollo, with its summits clad in dazzling snow. But to resume. The Kopaik Plain itself is almost absolutely flat right up to the feet of the hills which bound it, being, indeed, the dried bed of a lake. In ancient days, according to the interesting writings of Dr. J. G. Frazer, of Cambridge, this lake was a large sheet of water in the winter, and, in the summer, a series of marshes overgrown with sedge, with rivers winding through them and patches of dry land between. The lake was drained in very remote times by the people of Orchomenos, a town upon its banks, and the remains of the drainage works are still visible. The water enters from numbers of small rivers and streams gushing out of the surrounding mountains, and naturally escapes, singularly enough, into great caverns, of which there are many, called *katavothræ*. In the Middle Ages the drainage works appeared to have been allowed to fall out of repair; but recently a French company resumed the task; and, still more

recently, the work was taken up by the British Company, the Lake Kopais Company, which asked me to study the malaria for them. The whole bed of the ancient lake is now a great plain covered with crops of all kinds, which repay the cost of the engineering works. The water is at present discharged through adjacent valleys into the sea.

It was here that the malaria was so troublesome. The Lake Kopais Company has many hundreds of employees and tenants, who were constantly being attacked, although most of them were natives of Greece. It had not been found possible to keep accurate statistics of the annual number of cases; so that my first care was to make an estimate for myself of the amount of malaria present. This can be done with a fair degree of accuracy, without the help of statistics, in two ways—by ascertaining the proportion of people which, first, have the parasites of malaria in their blood, and, secondly, possess enlarged spleens. The first method was much used in India by Stephens and Christophers, who called the ratio of infected persons to the total population the *endemic index*. To obtain an absolutely correct figure by this means we must make an exhaustive microscopical examination of the blood of every person in the area under consideration; but this would be too laborious for practical purposes; and we must consequently content ourselves with an approximate valuation obtained by examining only a part of the local population. As shown by these observers, and by Professor Koch, it is especially the native children in a malarious locality who have the parasites in detectable numbers—the older people becoming comparatively immune. The blood of a number of unselected children is therefore carefully searched for the parasites, and the ratio so obtained is recorded as the approximate endemic index. For exact work a large number of children must be examined, as otherwise the margin of error, as shown by Poisson's formula, will be very considerable. For example, if 50 children be examined, and 25 of them be found to contain parasites, the error will be no less than 20 per cent.; so that the approximate endemic index will not be 50 per cent., as a hasty observer may think, but anything between 30 per cent. and 70 per cent. This fact is worth recalling, because it has been much overlooked in recent work on the subject, and because it shows how laborious the method really is. The second method, that of examining children for enlargement of the spleen, a thing which can be done in a minute, is much easier, and fairly trustworthy, provided that no other cause for splenomegaly is present.

With the valuable assistance of Dr. Kardamatis, General Secretary of the Grecian Anti-malaria Society, and of Mr. D. Steele, Manager of the Lake Kopais Company, in Greece, I was able to use both methods. The Company's houses are on the southern border of the plain, close to the site of the ancient Haliartos, where the Spartan Lysander was defeated by the Thebans, 395 B.C., and to the reputed grave of Alkmene, the mother of Hercules. The houses are built just where the slopes of Helikon begin to rise from the plain; so that they were obviously not too highly situated to be affected by the malaria. On examining 57 of the employees, most of whom were Greeks, we found enlargement of the spleen in 14 and the parasites in 9. But 5 of those that had parasites had no enlargement of the spleen, and must be added to the infected list, which therefore amounts to 19 out of the 57, or one-third. The majority of these people were adults; and many had come from other localities, so that the figures are not useful for statistics.

Our next care was to examine the people in some of the neighbouring villages. Out on the plain, about a mile or more from the Company's houses, there is the village of Moulki, containing some 350 inhabitants. The houses are closely clustered together, with very irregular and elementary lanes between them. Going to the village inn close to the school, we set to work and examined 80 persons, mostly children; first, by palpating them for enlargement of the spleen, and secondly, by making dried films of their blood for future microscopical enquiry. The scene was most interesting. Seated under a large tree, with the village priest as our patron and protector, we pricked and palpated the little ones, one by one. I never saw pluckier children. Scarcely one of them even winced at the vivisection. Nearly all of them were very intelligent, and many good looking; but, alas! most of them were far from well, and some looked miserably ill, emaciated and anæmic. The cause was speedily revealed. Out of 62 of the children, between the ages of 5 months and 14 years, no less than 35 were found to have enlarged spleens; and as no other cause of endemic splenomegaly, such as kala-azar, could be ascertained to be present in the locality, we could attribute the enlargement in these children only to malaria. This diagnosis has been fully confirmed by subsequent examinations of the blood films, which showed that the parasites existed in at least 17 of the 62 children at the time when the films were made. Of these 5 had an appreciable enlargement of the spleen, so that this number must be added to the number of spleen cases in order to arrive at the total yielding evidences of infection. Hence, out of the total 62 children, no less than 40 were certainly infected—a ratio of them of 64·5 per cent. This is, of course, the lower limit of the ratio, because it is quite possible, and indeed very likely, that the parasites were overlooked in some of the films. Such a ratio was unexpectedly high for any European country, and is almost equal to any that has been found in Indian or African children.

I may add that in many of the children the splenic tumour was very great, reaching almost to the crest of the ilium. This is important, in view of statements recently made in India to the effect that great splenic tumour is probably due to kala-azar, rather than to malaria. The former disease is apparently not present in Greece, the *Leishmania donovani* parasite never having been discovered there. Moreover, the Grecian cases were markedly different from the cases of kala-azar studied by me in Assam, in 1898, for the purposes of an official report. In not a single one of the former did we note any enlargement of the liver, so commonly seen in kala-azar; there was not the constant fever of kala-azar, the expression of the face was the unconcerned expression of malaria rather than the hopeless look of the deadly eastern disease; and lastly, the death-rate was far too small for the latter. Nevertheless, the splenic enlargement in a few of these cases of

pure malaria was, I think, as great as anything I saw in kala-azar. Of course, many of the children were shockingly anæmic and emaciated—not in any way, I was informed, from lack of food, nor, apparently, from the great prevalence of other diseases. The work was clearly that of the spirit of the marsh.

The next thing to do was to find the source of the malaria, or rather its carrying agents, the local Anophelines. As I have said, the Kopaik Plain is now drained and cultivated over its whole extent; but numerous small streams enter it from the surrounding hills, traverse it, and discharge into the main channels of drainage. These streams are swollen torrents in the winter, but in the summer often become trickles of water with occasional marshy borders here and there. Several such streams enter the basin near Moulki; but at that season (May to June) we could find no Anopheline larvæ in them, though some have been found subsequently, as we conjectured would happen with the advance of the dry season. But in addition to these streamlets there exists a long series of shallow pools suitable for the larvæ in the "borrow-pits" made by the engineers who constructed the railway embankment across the plain. Sure enough, in some of these pits close to Moulki we found the peccant insects, the larvæ of *Myzomyia maculipennis*, a known carrier of malaria. These gnats, rising from the pools, pour into the village and into neighbouring houses, such as those of the Company; become infected by biting the numerous infected children; and then infect any healthy persons whom they may subsequently bite. The old drama, now so well known, was obviously being played out before our eyes.

After having dealt with Moulki we examined the conditions at another village of about 575 inhabitants, situated several hundred feet high on the hills south of the Company's houses, and called Mazi. Out of 40 school children, we found enlargement of the spleen in 13, and the parasites of malaria in 16. Of those that showed the parasite, 7 had no enlarged spleen; so that we must add them to our total of infected children, giving 20 infected out of a total of 40 examined, that is, one-half. This is a large proportion, and we expected to find some breeding pools of Anophelines close at hand. In this, however, we failed; though we saw some lime pits which we thought might become suitable for the larvæ at a later season. But, nevertheless, there was no difficulty in explaining the malaria at Mazi, since we learnt that every year nearly the whole population descends to the plain for the harvesting in the month of August (the most malarious month) and bivouacs there for days or weeks. Doubtless the people of Mazi become infected on these occasions; though I suspect that breeding pools will be found close to the village by more extensive search.

My time being very limited, we could make only hasty studies at other spots. Across the Plain lies the village of Skripou, on the site of the ancient Orchomenos. Here we found splenic enlargement in exactly half of 40 school children examined; but had no time to take blood films. The village is evidently intensely malarious. We had time to look for mosquito larvæ only in one spot, the beautiful Fountain of the Graces, which gushes out of the mountain and spreads in a small marsh near at hand. Here, again, we found the shameless insects desecrating the divine spot. What must have happened when the Graces bathed there I cannot say. We saw only washerwomen and geese.

Thus on the borders of the Kopaik Plain we had examined 142 children and had found certain evidence of malaria in no less than 80, or 57 per cent., a very high malaria rate. But we soon obtained evidence that the disease is not confined to this low-lying area. Livadhia is a beautiful little town of 6,250 inhabitants, situated 540 feet up the spurs of Helikon, some miles beyond the western end of the Plain and facing Mount Parnassus. It begins at the romantic gorge where was the Oracle of Trophonios in former days, and where the two springs of Lethe and Mnemosyne—Forgetfulness and Memory—now flow out of the rock. Notwithstanding the height of the situation and the absence of any apparent marshes close at hand, we found enlargement of spleen in 16 out of 100 school children here. The infection is probably obtained in lower areas outside the town; but we had no time to make any search for the Anophelines. We spent some hours also at Thebes itself. This famous place, which used to contain 40,000 inhabitants now contains only 4,780. Situated on a rocky eminence in the midst of a large plain, the historic Kadmeia, it is considered to be very fairly healthy; and indeed we found enlargement of the spleen in only one child out of 50 examined; and failed in obtaining any larvæ of Anophelines in several small pools round the base of the renowned citadel. Such researches carried out on the spot where lived Pindar and Epaminondas, where Theban, Athenian, and Spartan had frequently mingled in battle, and where angry Alexander wreaked his vengeance, were "of the age." I am not certain whether the little wriggler of the puddles had not been a worse enemy to Thebes than was the great conqueror. One remains, the other has passed away for ages. If Diogenes had possessed our present knowledge he might have made a still more caustic reply to his powerful visitor.

Thus, altogether, out of 292 unselected children examined by us in five different places, we found unmistakable evidence of malaria in 97, or one-third. In addition to the children we examined 18 adults at Moulki. As is now well known, the adult natives of a malarious locality become comparatively immune, their spleens returning to the normal size, and the parasites becoming extremely scarce in their blood. Nevertheless, we found signs of malaria in 4 of these adults, but, of course, such figures are not useful for estimating the endemic index. Including all, we found certain evidence of malaria in 120 out of 367 persons, or 32 per cent. The figures for the children, however, give a reliable and high malaria rate, especially when it is remembered that they were collected at the beginning of the summer, *before the annual malaria season had commenced*. Later in the year the endemic index would certainly have been still higher. If, moreover, we had examined the blood of the 200 children dealt with at Orchomenos, Livadhia, and Thebes, we should certainly have been able to add many other cases of infection to our list; while lastly,

we should remember that in all cases of malaria the parasites frequently become temporarily too few for detection by the microscope. Our total estimate of 33·2 per cent. infected children must therefore be much below the maximum ratio, and may be looked upon as a minimum ratio. The statistical corrections by Poisson's formula works out at 7·7 per cent.; so that we have finally for the five localities, Moulki, Mazi, Orchomenos, Livadhia, and Thebes, a minimum child-malaria rate of between 25·5 per cent. and 40·9 per cent. The truth is, probably that at Moulki and Orchomenos *all* the children are really infected in the autumn.

With regard to the number of breeding places of Anophelines we found them only in two small pools, one at Moulki and one at Orchomenos; and the former of these was immediately drained away by Mr. Steele, of the Lake Kopais Company. The season, however, was early, and our search far from exhaustive. Many more pools will, of course, be found; but, nevertheless, I infer that the amount of breeding surface per square mile of country is extremely small, so that anti-propagation measures ought to be correspondingly cheap.

Such were the results of my own observations; and I will now give briefly some figures which I obtained for the whole of Greece. Within the last year or two there has been founded at Athens an admirable Malaria Society for the study of such questions. It is under the patronage of H.M. the King of Greece, and consists of many enthusiastic members. One of these is my friend, Dr. Savas, Professor of Hygiene at the University of Athens, and Physician to the King of Greece; and the General Secretary is my friend Dr. Kardamatis, who gave me so much assistance at Lake Kopais. I can testify to the complete knowledge of the subject possessed by both of these gentlemen—whom I mention more particularly than their colleagues, because I was brought more especially into contact with them; to their zeal in the cause, and to their philosophic grasp of the importance of the malaria question for their country. From them I obtained the following approximate figures for the whole of Greece:—

Population of Greece	2,433,806
Average annual number of cases of malaria	250,000
Average annual number of deaths from malaria	1,760
Number of cases of malaria during 1905	960,048
Number of deaths from malaria during 1905	5,916

These figures are, I think, as sound as any that can be collected from statistics. Malaria is a very difficult disease to deal with in this way; because it does not consist of a single severe attack demanding immediate medical assistance, but rather of a series of comparatively slight attacks extending over a period of years, and, moreover, occurring principally in young children. Many cases do not find their way into the returns at all; while, on the other hand, relapses must be frequently entered as fresh infections. As for the death-rate, comparatively few cases die simply of malaria, but many are carried off by intercurrent pneumonia or diarrhœa, or perish gradually from anæmia, under which headings the mortality is often recorded. The figures given above, however, agree entirely with my own estimate of the endemic index round Lake Kopais; and I believe that if similar methods could be used all over Greece—if all the children in the country could be examined—it would be found that an extremely large proportion of them are constantly infected. Last year was a very bad year, with a recorded death-rate of 2·4 per thousand of the population. Nor is the malaria of a benign type in Greece. On the contrary, I was informed by all the gentlemen mentioned above and also by a number of medical men whom I met at Thebes and Livadhia, that pernicious attacks are very common, and that the most serious form, that of blackwater fever, is extremely common. Such facts are recorded also in the writings of Kardamatis, Savas, and other able Greek observers. The disease is therefore extremely, if not shockingly, rife in the country—much more so even than in Italy. Dr. Savas told me that from some statistics which he had studied the number of cases and deaths in Greece are half again as numerous as in Italy for equal numbers of people. All species of the parasites are to be found in Greece. In our own studies the mild tertian parasite occurred most frequently, the so-called malignant species next commonly, and the quartan least of all—but not rarely. As I have said, blackwater fever, the worst form of malaria, has been very common in Greece. Regarding the species of Anophelines, which carry malaria in the country, Dr. Savas told me that out of 1,839 of these insects, 1,778 were found to be *Anopheles maculipennis*, 21 to be *Anopheles bifurcatus*, and 20 to be *Pyretophorus superpictus*, all well-known agents of the disease.

Now, what must be the effect of this ubiquitous and everlasting incubus of disease on the people of modern Greece? Remember that the malady is essentially one of infancy among the native population. Infecting the child one or two years after birth, it persecutes him until puberty with a long succession of febrile attacks, accompanied by much splenomegaly and anæmia. Imagine the effect it would produce upon our own children here in Britain. It is true that our children suffer from many complaints—scarlatina, measles, whooping-cough—but these are of brief duration and transient. But now add to these, in imagination, a malady which lasts for years, and may sometimes attack every child in a village. What would be the effect upon our population, especially our rural population—upon their numbers and upon the health and vigour of the survivors? It must be enormous in Greece. People often seem to think that such a plague strengthens a race by killing off the weaker individuals; but this view rests upon the unproven assumption that it is really the weaker children which cannot survive. On the contrary, experience seems to show that it is the stronger blood which suffers most—the fair, northern blood which Nature attempts constantly to pour into the southern lands. If this be true, the effect of malaria will be constantly to resist the invigorating influx which nature has provided; and there are many facts in the history of India, Italy, and Africa which could be brought forward in support of this hypothesis.

We now come face to face with that profoundly interesting subject, the political, economical, and historical significance of this great disease. We know that malaria must have existed in Greece ever since the time of Hippocrates, about 400 B.C. What effect has it had on the life of the country? In prehistoric times Greece was certainly peopled by successive waves of Aryan invaders from the north—probably a fair-haired people—who made it what it became, who conquered Persia and Egypt, and who created the sciences, arts, and philosophies which we are only developing further to-day. That race reached its climax of development at the time of Pericles. Those great and beautiful valleys were thickly peopled by a civilisation which in some ways has not since been excelled. Everywhere there were cities, temples, oracles, arts, philosophies, and a population vigorous and well trained in arms. Lake Kopais, now almost deserted, was surrounded by towns whose massive works remain to this day. Suddenly, however, a blight fell over all. Was it due to internecine conflict or to foreign conquest? Scarcely; for history shows that war burns and ravages, but does not annihilate. Thebes was thrice destroyed, but thrice rebuilt. Or was it due to some cause, entering furtively and gradually sapping away the energies of the race by attacking the rural population, by slaying the newborn infant, by seizing the rising generation, and especially by killing out the fair-haired descendant of the original settlers, leaving behind chiefly the more immunised and darker children of their captives, won by the sword from Asia and Africa?

Those who have read Dr. W. North's fascinating book on "Roman Fever" (Sampson Low, Marston and Co., 1896) will remember the suggestion that the depopulation of the Campagna was due to the sudden introduction of malaria by the mercenaries of Sylla and Marius, and so recently as 1866, as we know from the works of Dr. Davidson, of Edinburgh, malaria entered and devastated the islands of Mauritius and Reunion, either the mosquito or the parasite having been then brought in from without. Similarly, could it not have been introduced into Greece about the time of Hippocrates by the numerous Asiatic and African slaves taken by the conquerors? Supposing, as is probable, that the Anophelines were already present, all that was required to light the conflagration was the entry of infected persons. Once started, the disease would spread by internal intercourse from valley to valley, would smoulder here and blaze there, and would, I think, gradually eat out the high strain of the northern blood.

I cannot imagine Lake Kopais, in its present highly malarious condition, to have been thickly peopled by a vigorous race; nor, on looking at those wonderful figured tombstones at Athens, can I imagine that the healthy and powerful people represented upon them could have ever passed through the anæmic and splenomegalous infancy (to coin a word) caused by widespread malaria. Well, I venture only to suggest the hypothesis, and must leave it to scholars for confirmation or rejection. Of one thing I am confident, that causes such as malaria, dysentery, and intestinal entozoa must have modified history to a much greater extent than we conceive. Our historians and economists do not seem even to have considered the matter. It is true that they speak of epidemic diseases, but the endemic diseases are really those of the greatest importance.

The same cause works the same evil in modern Greece. Though the country has been freed from the Turks for seventy years, and enjoys what is condered to be (though personally I doubt it) the best form of government, yet its population has not increased very much. Athens has about 130,000 inhabitants, and Patras, the next largest city, about 40,000; and the other towns are scarcely more than large villages. The rural areas contain small and poor, but not destitute, hamlets; but what strikes one most in them is the absence of villas and of large hotels. Few of the wealthier people seem to live in the country. A gentleman of Athens told me that he bought a shooting-box, but that he was attacked by malaria when he went to stay there. The inns are comparatively small and shabby, and not likely to be frequented by many modern tourists, and the methods of communication are primitive. This is very surprising, because one would think that such a country would be the Mecca of all the tourists of Europe and America, who would pour their millions of pounds into it, just as they do into Switzerland. But, of course, the reputation of unhealthiness possessed by many of the rural tracts is fatal; the tourist thinks twice about going to them, and the innkeeper hesitates about spending his capital in a locality where he and his children may expect to be frequently ill.

The whole life of Greece must suffer from this weight, which crushes its rural energies. Where the children suffer so much, how can the country create that fresh blood which keeps a nation young? But for a hamlet here and there, those famous valleys are deserted. I saw from a spur of Helikon the sun setting upon Parnassus, Apollo sinking, as he was wont to do, towards his own fane at Delphi, and pouring a flood of light over the great Kopaik Plain. But it seemed that he was the only inhabitant of it. There was nothing there. "Who," said a rich Greek to me, "would think of going to live in such a place as that?" I doubt much whether it is the Turk who has done all this. I think it is very largely the malaria.

Now, regarding the remedy. Science has, of course, shown absolutely that the disease is carried by gnats, and, in doing so, has indicated several methods of prevention. First, there is the method of excluding gnats by the careful use of mosquito nets and wire gauze screens to the windows—useful for the houses of the rich, but too costly and troublesome for the poor. Then there is the method of Koch, the cinchonisation of all the patients, by which they themselves are benefited, while the gnats do not become infected and therefore do not spread the parasites; but this implies rigorous dosing with quinine for months—a thing which patients and the mothers of children will not submit to. But the method which I first suggested and elaborated in 1899, namely, the reduction of mosquitoes, is the one which I prefer, and the one which, after seeing the conditions in Greece, I prefer more than ever. It is, of course, the old Roman plan of drainage against malaria, with this important differ-

ence, that we are now no longer compelled to drain the whole surface of a malarious area, but only those small pools in which the Anophelines breed. This method has the immense advantage that it can be carried out by local authorities without troubling the people; while in the end it is sure to be more economical and lasting in its effects than other methods which, I think, are apt to cause waste both of money and effort. To Greece it is most especially applicable. There, the rainy season is the winter, when the mosquitoes do not breed; so that in the arid summer they can find only very few suitable breeding pools. So much the easier and cheaper will it be to treat these. They can be rendered uninhabitable for the larvæ by drainage, by filling up, by deepening, by dragging the weeds, and in the last resort by periodic oiling. Where carried out with intelligence and loyalty, as in Havana, the Federated Malay States, and Ismailia, the work has proved comparatively easy and cheap, while the results (now so well known) have been of the most brilliant kind. I think that Greece, owing to the scarcity of surface water suitable for the larvæ in the summer, will be easier to deal with than any of these places—easier even than Ismailia, with its irrigation system. It will be strange indeed if so intelligent a nation cannot carry out such simple measures in order to rid itself of a plague which has oppressed it for ages.

The Grecian Malaria Society has commenced the work with energy. It has investigated local conditions; has issued numerous tracts to the people; has urged railway companies to screen stations, and Government to undertake drainage. Dr. Savas suggests Government regulation of the sale of quinine in order to improve and cheapen the drug—a most necessary item. At Athens, where malaria exists only along the bed of the Ilissos, the stream has been "trained" in many places. Presently I hope we shall see a survey made of the malaria and the local breeding places in the whole of Greece, preparatory to a general onslaught on the foe. When I was in Athens I had the pleasure of speaking to M. Theotakis, the Premier, and Mr. Boufidis, the President of the Chamber, and am sure that the Government will do its best to support the campaign. But the Society will have to fight many enemies, chief among which will be the incredulity and indifference of the public. I have therefore suggested that we in Britain may help it by doing something to show our support of it. The Liverpool School of Tropical Medicine has accordingly offered its assistance, which has been accepted by the King of Greece; and under the patronage of H.R.H. Princess Christian, we have opened a list of supporters, which now includes many eminent names, beginning with those of the Greek Minister in London, the British Minister in Athens, the Presidents of the Royal Society and the British Academy, the Royal College of Physicians, and many Greeks residing in Britain. It often happens that a little foreign support will do more to encourage a cause than much local effort can do. If any of you wish to join us we shall welcome you most heartily. You have but to write a note to me or to our Secretary, A. H. Milne, Esq., B10, Exchange Buildings, Liverpool.

When matters are in proper train, every year will see the removal of a number of the little marshes which are so injurious to the country—every year will see a decrease in the malaria. I venture to say with confidence that, give us but the necessary means—and we do not require much—there is no country in the world from which we could not extirpate the disease. Hitherto we have contented ourselves with diminishing it in isolated towns. Let us now deal with whole nations. Remember that it has actually been banished from Great Britain, almost by unconscious agencies. We have only to imitate those agencies consciously. What a triumph it will be for that great science, of which all of us are the humble votaries, if she can wipe out this miasm, this defilement, from an entire country. I will not hesitate—such is our ambition. And that country is Greece.

I asked a Greek friend why his countrymen did not restore the Parthenon. He replied it was because they were unwilling to touch the sacred ruins without the assent of the whole world, to whom they belonged. So also Greece belongs to the whole world. We all share in her troubles and should do our best to relieve them. Many years have passed since Byron gave his life for Greece. He attributed her misfortunes to loss of liberty. Perhaps so; but I think that an enemy more inveterate than the Turk has also destroyed her. Not least among the nations, Britain has studied to help her against her human enemies. Should we not help her now against the more potent enemy which we have discovered. That Science which, more than two thousand years ago, she created is at our side urging us on. We have no doubt of the result—we need only to nerve the arm to strike.

Gentlemen, it was my good fortune to stand the other day at a spot from which can be seen within eyeshot the birthplaces of science, art, philosophy, the drama—of Europe, of our modern civilisation. It was a great rock rising in the midst of a city built on a plain—not a boundless uninteresting expanse, but a plain, defined as such by a cincture of beautiful mountains. I have known many of the loveliest scenes of this wonderful earth, but nothing altogether equal to the Attic plain. The rock was the Acropolis; and the setting sun flooded it with light. Upon it rose those ruins which are unsurpassable, unpaintable and indescribable, because they were built, not only for themselves, but for the visions which surround them—the Propylæa, the Erechtheion, the Parthenon. And who was the god for whom that temple was built—which of all those gods, who are not dead as some imagine, but who live now and will live for ever until, as the poet says, "the future dares forget the past"—who live because they are the everlasting types of our own spirit? That goddess whose birth and victory were recorded on the pediments of the Parthenon; who sprang, not from the common zygosis of Nature, but full-armed from the head of Zeus at the touch of Fire and Toil; who conquered the Deep himself. Study her attributes, perceived and recorded in legend by the sages who lived before history was born, and we shall know her. Without human weakness, she led Ulysses through the dangers of the Deep, she gave Perseus the weapons with which he slew the monster of the Deep, she destroyed the city of the Deep, she made Athens triumph over the Deep,

and to-day has lifted man in a few centuries from the Deep to heights unimagined before—Science herself. The Parthenon was the temple of Science. The great figure of Science, standing before it, dominated the whole of Greece. At its gates, even, stood the figure of Hygeia, the Science of Health, whom we now invoke. Science is the goddess whom we serve, as did the ancient Athenians, because we know that she and she alone can save us from these elements of the Deep which oppress us. We are her servants. We honour not the baser gods—the quack remedies, the sham philanthropies, the false knowledges, the mock philosophies, the whining pities, the lying politics which keep men down in the depths. We acknowledge only the intellect which sees the truth and smites the evil. Let us pray Pallas Athena to revisit the land where she was born.

OPERATION LEUCOCYTOSIS.

By P. N. Gerrard, B.A. B.Ch. B.A.O., M.D.(Dublin), D.T.M.H.(Cantab).

Federated Malay States.

As it falls to the lot of surgeons very rarely to profit both their patients and themselves, by what I must insist upon calling a surgical error, the case quoted below, in which both of these happy contingencies occurred, may be of interest to the profession.

Polgadu, aged 23, coolie, Tamil, male, was admitted to Parit-Buntar Hospital on May 29th, 1906, complaining of abdominal pain, and constipation for two days. The abdomen was noted as being distended and tense.

My absence at the time of his admission, on sick leave, prevented me from seeing the case until June 16th, on which date the following symptoms presented themselves:—

The patient was emaciated and evidently suffering, his complaint being entirely referred to the lower part of his abdomen. His temperature rose at night to 102°, and was usually 99° in the mornings. Bowels constipated, urine regular and healthy, save that on the day of his admission it had to be drawn off by catheterisation; his mouth was dry, and his tongue was dry and somewhat furred; his pulse was rapid and atonic.

On examination the abdomen was hard and exquisitely tender, more especially in the middle hypogastrium and bladder region, where a tenseness and an apparent tumour with ill-defined edges existed.

The patient was so ill that I decided upon an exploratory laparotomy next morning.

The diagnosis at that time lay, to my thinking, between the following:—

(1) An antero-cystic abscess; the symptoms in the last case in which I operated having been very similar to those presenting in this case.

(2) An abscess of the appendix, presenting in the median line and involving the pelvic peritoneum.

By analogy I was much inclined to the former.

The patient, after proper preparation, was placed on the table, chloroform was administered, catheterisation performed, and an incision about 2½ ins. long made in the median line about 1 in. above the pubes.

Having made the preliminary incision I cut through the layers of what I believed to be greatly thickened peritoneum (which I had expected to encounter), and in the bottom of the wound what was apparently a coil of intestine presented; as the contents of this protrusion were apparently clear, I came to the conclusion that it was a cyst or hydatid, superficial to the bladder, and incised it, when I obtained clear urine. Passing a catheter, there was no doubt left of my error. On exploring the bladder, however, an interesting condition revealed itself.

The bladder appeared to be divided into two sacs, an anterior and a posterior, or, as the patient lay, a superior and an inferior, the superior being practically cut off or delineated from the inferior by the presence of an oval tumour, formed apparently by distended peritoneum pressing against the posterior surface of the pubes.

The bulging peritoneum contained at least fluid, if not pus, and nothing remained for me to do except to suture carefully the bladder wound, to tie in a catheter for drainage, and to proceed to the major undertaking of opening the peritoneum just below the umbilicus.

I had hardly completed the cystic suture when the patient ceased to breathe, the pulse became intermittent, and all the signs of impending death occurred. Strychnine and ether were promptly administered, and I had already commenced artificial respiration by thoracic pressure, but as no response was apparent I started to respirate by the Silvester method; this, to my surprise, could not be carried out, as all the patient's muscles were in a state of tonic contraction. The dose of liq. strychnine administered was 4 minims. I continued for about ten minutes the intermittent thoracic pressure, but as the pulse apparently failed, respiration showed no signs of becoming re-established, and the pupils became fixed, I gave the case up as dead, and went to wash my hands, full of vain regrets and disappointment. Before thirty seconds had elapsed, however, respiration recommenced, the pulse returned, and the patient became sufficiently well to be removed to his ward, but not, in my opinion, sufficiently recovered to proceed to the completion of the operation.

Owing to a sudden outbreak of cholera in the district some miles away I was unable to see my patient until Monday, the 18th. His temperature had fallen to normal I found, after the operation, and had remained normal, his abdomen was soft, and he was free from pain, his general condition was good, and he asked for full diet; his pulse was good, his tongue clean, the bladder had acted normally, and he appeared to be on the road to recovery from all his ailments.

The case made an uneventful recovery, and primary union of the bladder and of the superficial wound took place. He left hospital, fat and well, about three weeks after his operation.

I believe the symptoms to have been due to an atonic and distended anterior portion of the bladder, that peritonitis with effusion was present in the first instance, and that the case was cured by a determina-

tion of blood supply, and a concomitant local leucocytosis to the pelvis.

This case might well suggest, in these days of cleanliness, a more frequent exposure of the peritoneum in cases of effusion from any cause, with a view to the absorption of the fluid by means of stimulation of the pelvic lymphatics and blood supply.

To the Editors of the JOURNAL OF TROPICAL MEDICINE.

DEAR SIRS,—I beg to forward an account of an epidemic of dengue which attacked Port Sudan this year—Port Sudan being a new town, and the seaport of the Sudan.

I may say that dengue fever does every year show itself at Suakim, although not there located in the text-books. We have had also this year a very sharp outbreak of quinine dengue at Halfa. I presume that it made its way along the new Suakim-Atbara Railway to this inland town.

There are so many fevers out here, diagnosed as simple fever, simple continued fever, sun fever, local fever, &c., that it is a relief to get one disentangled and nailed down and labelled, so to speak. There is another Sudanese fever, although rather a twenty-one days' fever than an eight day, which may be mistaken for typhoid (but it is without abdominal symptoms), or Malta fever (but it is without throat or joint symptoms); it relapses, however, and differs from malaria, in that it does not yield to quinine.

It might be called low tropical fever, for it requires change of locality for its cure. It also requires naming. It is, I think, different in its temperature chart from the typhoid type, in that the fever is rather of the intermitting type than the remitting.

Yours faithfully,

J. B. CHRISTOPHERSON, M.D., M.R.C.P., F.R.C.S.,
Director Sudan Medical Department and Physician to H.E. the Governor-General of the Sudan.

Sudan Government,
Medical Department, Khartoum,
September 25th, 1906.

DENGUE IN PORT SUDAN—RED SEA PROVINCE, SUDAN.

By SELIM SAIGH, M.D.
Medical Officer in Sudan Medical Department.

THE disease appeared this year as an epidemic in Port Sudan, the new seaport of the Sudan. The first case entered the hospital on May 29th, 1906. From that time it increased rapidly, affecting one part of the town, then the other, so that by the end of August a very large number had been attacked.

It affected equally white and coloured people, and both sexes, and men of every age, except young infants. One attack did not confer immunity, many patients having more than one attack. The incubation period was from two to four days.

Etiology.—Probably the carrier of dengue is the mosquito. The present epidemic affected chiefly the houses where it was found, and the disease reappeared when there was an increase of mosquitoes in the town.

It was especially remarkable that all people living in the hospital escaped, though by that time the wards were full of cases of dengue. The hospital was the only place free from mosquitoes: though we were very careful to destroy the larvæ present in our water; this was the only precaution that was taken.

Onset.—The onset is very sudden, usually coming on in the afternoon. Prodromata are rare, and when present they consist of headache, anorexia and rheumatic pains. The disease is rarely ushered in by a chill. A patient describing his attack said: "I have been out to work all day, feeling the same as usual; about sunset I had headache, and feeling tired I sat on a chair to rest; suddenly I began to have pains all over, and half an hour later, when I had to go home, I was so stiff that two men had to support me all the way home."

Such onsets are very common, and it is usually in such a manner that the disease begins. The fever then develops rapidly, and with it the headache, and the pains in the neck and eyeball increase; the pains in the loins, thighs, knees, and calves are very characteristic and are almost always present; in a word, all the body is stiff, and the least movement is painful; during the night the patient is unable to sleep and very restless.

Circulatory System.—Dengue does not affect the heart except by raising the pulse from 90 to 120, and in very severe cases to 130. Sometimes there is profuse epistaxis, and this often relieves the headache and brings down the fever.

Respiratory System.—The most important difference between influenza and dengue lies in the fact that the latter does not give rise to pulmonary symptoms. There might in some cases be a mild laryngeal catarrh and bronchitis. The respiration during an attack of dengue is accelerated.

Digestive System.—There is often with the first symptom very severe pain in the stomach, with vomiting, but these usually subside after the first two or three days. The tongue is coated during the attack, and begins to clear when the fever falls: there is a complete loss of appetite. During the first three or four days there is constipation, which is sometimes followed by diarrhœa, in some cases persisting for a time after the attack has subsided.

Spleen and Liver.—The liver and spleen are not affected; in two cases there was an enlarged spleen, but this was probably due to the fact that the patient had malaria before.

In the beginning of an attack there is often a deep flushing of the face, but the real eruption does not begin until the third or fourth day. It is present in most cases, and consists of roseolæ of the size of a pin's head, dark in colour, coalescing and forming patches of different sizes; this eruption affects the face, neck, back, forearm, and hands, in some cases extending to the thigh. The eruption begins to fade when the fever goes down, and in a short time the skin desquamates, peeling off in small flakes.

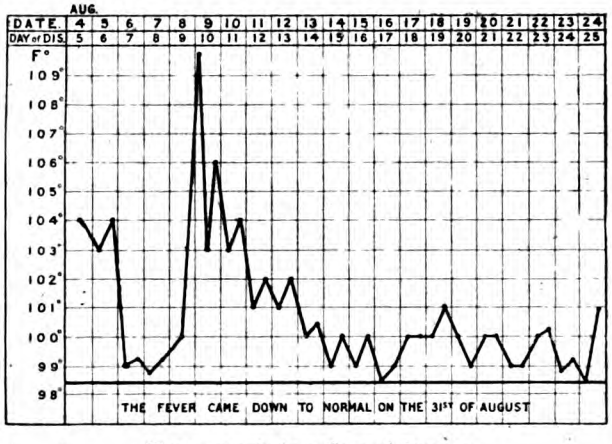
Kidney and Urine.—In the great majority of cases the urinary system is not affected, a few patients had albumin, and all of these had an attack of epistaxis.

Nervous System.—The pains in the head, neck and eyes are the only troubles set up in the nervous system.

General Course of the Fever.—After the onset the fever increases rapidly, rising as high as 103° or 104,° and is continuous in character, there being not more than one degree difference between the morning and the evening temperature. With the increase of the fever all the symptoms augment in severity; this goes on for five or six days, the fever falls then by crisis, usually in the afternoon. The pains and the rash then begin to disappear, and the patient becomes convalescent.

In mild cases the fever falls to normal in the second or third day, such cases have mild symptoms, but in severe cases, especially when there are complications, the fever is protracted, falls by lysis, and recovery is very slow.

An attack leaves the patient very weak and debilitated, the pains in the thigh, knees and calves may persist for some time, rendering motion painful and difficult, but gradually the tongue gets clean, the appetite improves, and the patient is able to resume his work.



Hyperpyrexia in a Case of Dengue.

Complication.—The most severe complication is hyperpyrexia, but luckily it is a rare one, and appearing in the very hottest part of the year; in these cases the patient, after a protracted attack of dengue, suddenly develops hyperpyrexia, the temperature rising as high as 108° or 109°, this sudden attack usually happens between 1 and 3 p.m., a comatose condition supervenes, with a very weak pulse and stertorous breathing; if he is able to survive the high temperature he will probably have another rise in the evening, but this time only to 105° or 106°. The next day his temperature reaches 104°, falling down very slowly by lysis. Such attacks are always followed by severe bronchial catarrh, their duration is very protracted, leaving the patient weak for a long time.

Mortality.—Only two cases died of dengue, both of them Europeans. Both had long standing emphysema. After a protracted attack they developed hyperpyrexia with all its concomitant symptoms, and succumbed in a very short time.

Death was caused by asphyxia, as the bronchi were full of mucus, rendering respiration impossible. Probably hyperpyrexia, due to the fact that the disease affects the brain and meninges. The other complications have already been mentioned. They consist of rheumatic pains, epistaxis, and, rarely, albumin in the urine and bronchitis.

Diagnosis. — The only disease which resembles dengue is influenza, but the roseolar eruption, the lack of pulmonary symptoms and the rheumatic pains render the diagnosis easy.

Treatment.—The disease has a special course to follow, and there are medicines to help it abort, or cut it short. I found that the following prescription is effective by relieving the pains.

℞	Sod. salicylate	10 grs.
	Sod. bicarb.	10 grs.
	Tinct. aconit.	2 mins.
	Aqua.	1 oz.

Liniment of belladonna and stimulants applied externally might also relieve the pain. As to hyperpyrexia, immediate sponging with ice till the temperature falls to 99° or 100°, with strong doses of strychnine; this is to be repeated if the temperature gets higher again. As a tonic nux. vomic., quinine, and iron, are necessary during convalescence when the attack has been severe, followed by change of climate as soon as the patient is able to move.

"Lancet," October 20, 1906, p. 1,064.

"A New Aspect of the Pathology and Treatment of Leprosy.

Black, Dr. Robert Sinclair. In a short but extremely suggestive and interesting paper, the author details some conclusions he has reached during seven years' experience of the Cape Government establishment for the isolation of lepers on Robben Island.

Dr. Black entirely disbelieves in Mr. Jonathan Hutchinson's fish-eating theory of the disease, and appears to regard contagion as the only possible method of communication. He believes that in most cases the bacilli first attack the nasal mucosa, causing a mild chronic rhinitis which is rarely if ever noticed by either the patient or his medical attendants as a symptom of leprosy.

It is in this condition that the disease is usually communicated to others, and Dr. Black believes that the early recognition and treatment of this condition would go far to limit the spread of the disease, not only to others, but also within the tissues of the person already attacked, believing that the lesions are at first superficial and probably remediable by surgical measures.

He further believes that leprous erythema is caused by a toxæmia, the toxins being, however, derived not from the leprous bacilli, but from the abundant staphylococci and streptococci which are always to be found in leprous ulcers.

"Münch. Med. Woch.," July 24, 1906.

Agar-agar in Chronic Constipation.

What seems far-fetched physiological reasoning has been applied to the treatment of chronic constipation. Agar-agar in one or two tablespoonfuls with (when it is called regulin) or without cascara, is administered daily for a few days until the bowels act, when it is gradually reduced to a teaspoonful. The idea is that the agar-agar swells in the intestine, and promotes peristalsis by the bulky nature of the contents it induces.

5.—Change of address should be promptly notified.

6.—Non-receipt of copies of the Journal should be notified to the Publishers.

7.—The Journal will be issued on the first and fifteenth day of every month.

Reprints.

Contributors of Original Articles will be supplied FREE with six copies of the Journal if a request accompany the MS. If reprints are required they will be supplied by the publishers, if the order is given with remittance when sending the MS. The price will be as below:—

50	Copies of four pages,	5/-;
100	,, ,,	6/-;
200	,, ,,	7/6;
50	Copies beyond four up to eight pages,	8/6;
100	,, ,, ,,	11/-;
200	,, ,, ,,	14/6.

One page of the Journal equals 3 pp. of the reprint.

If a printed cover is desired the extra cost will be for 50 Copies, 5/6; 100 Copies, 6/6; 200 Copies, 7/6.

NOVEMBER 15, 1906.

THE CASE OF THE INDIAN HOSPITAL ASSISTANTS.

NOT long ago we had occasion to note the dissatisfaction of the vernacular students of the Lahore Medical School with the conditions under which they worked, and it was pointed out that the agitation could not in any sense be described as factious, as it was undoubtedly based on legitimate causes of dissatisfaction.

The last received issue of the *Pioneer Mail* now brings us the news that "the Medical School Club of Agra, acting on behalf of all medical students and Hospital Assistants, has issued a number of memorials to all the provincial heads of the medical departments in India, praying for an amelioration in the pay and prospects of a class of public servants who, in the opinion of the Club, do not enjoy that measure of official consideration and patronage to which they are entitled. The complaint is confirmed by the various official reports, which agree in emphasising the necessity of raising the status of Hospital Assistants. In spite of these repeated representations, however, nothing seems yet to have been done. It is stated that the demand on the services of hospital assistants has of late grown beyond their ability to meet it. In many cases, owing to the outbreak of plague, cholera, or some other epidemics, their leave of absence is stopped, while even normally their pay scarcely corresponds to the amount of work expected from them."

It will be observed that the memorialists are acting in a perfectly moderate and constitutional manner, in pleasant contrast with the methods usually adopted by the Indian college youth when he thinks himself aggrieved; and, apart from the traditional loyalty of the Hospital Assistant class, this may be taken as an indication of their conviction of the goodness of their case.

It cannot be denied that the class is wretchedly paid in proportion to the amount and responsibility of the work expected of it, and the scale of remuneration, moreover, compares ill with that accorded to public servants, drawn from a similar class of Indian society, belonging to other departments.

The pay of civil Hospital Assistants "with English qualification," *i.e.*, if capable of reading and writing English, commences at Rs. 25 *per mensem*, and rises to Rs. 55 (or from £20 to £44 *per annum* about.)

In the executive branch of the Civil Service, the "Teshildars," whose nearest European representatives would be French *maires*, commence at Rs. 50 and attain to Rs. 250 per mensem, equivalent to £40 to £200 per annum. In the forest department the pay of the corresponding subordinates, or "Rangers," commences at Rs. 50, and reaches Rs. 150, with the probability of promotion to "Extra Assistant Conservator," drawing, in the highest grade, Rs. 350, or about £280 per annum. In the police department, the pay of inspectors runs from Rs. 50 to Rs. 200 per mensem.

Now, the Hospital Assistant class are undoubtedly fully the equals of the members of the contrasted departments in intelligence and education, and are drawn from much the same strata of native society, those, in fact, which most nearly correspond to our "middle classes."

The teshildars, no doubt, usually belong to more influential families than those from which the other departments are recruited, but are in no way superior in education and intelligence, while, on the other hand, the inspector of police is usually promoted from the ranks, and though selection for promotion doubtless implies ability above the average, they are often of humbler social origin than the medical subordinate. Like the hospital assistants, the subordinates of the forest department are specially trained in a Government college, mainly at the public expense.

It is difficult to see any just reason for this extraordinary difference of treatment, for it will be seen that the medical subordinate's pay finishes pretty much about the scale at which the others commence, but the depreciation of medical work runs right through all branches of the department, the pay of assistant surgeons, though fully qualified medical men, comparing almost as poorly with that of the corresponding "Extra assistant commissioner" of the executive Civil Service. The excuse given would probably be the old tale of emoluments gained in private practice, but on this matter the hospital assistant, in common with all other exponents of the European system of medicine, has been hardly hit by the wave of unpopularity and distrust that has possessed native society against all its professors as the outcome of plague and the

measures adopted to cope with it; and it is probably this circumstance that has brought the service to the stage of petitioning Government for better treatment.

Even allowing for the cheapness of living in India, Rs. 25 per mensem is starvation pay for a man who has been raised by education to an entirely different standard of civilisation from that of the ordinary coolie, and it is no better than cruelty to take an Indian lad, and after converting him into a civilised and thinking man, to pay him somewhere about the wages of a decent butler or cook. It must not be forgotten that practically all are married men with families.

During the recent troublous times of famine and plague in India, the loyalty and pluck of our medical subordinates has been above all praise. They undoubtedly form the backbone of our system of medical relief, and we trust that the powers that be will turn a sympathetic ear to the petition alluded to in our Indian contemporary, and will do something to alleviate the hardships of a hardworking and estimable body of men.

AN APOLOGY.

I REGRET to learn that the letters and notices concerning the memorial to the late Professor Schaudinn were inserted in the JOURNAL OF TROPICAL MEDICINE of November 1st, under a misapprehension. It appears that the letters I received were intended for private circulation only, and those who have charge of the memorial in this country are deeply concerned that the letters were published. Seeing that the letters were printed and not marked private or confidential, it did not occur to me that they were not public property.

I beg to apologise for the error I made in publishing the correspondence, but it was done with the intention of advocating the cause so many of us have at heart, namely, a fitting testimony to the memory of a man all must revere. I write this in the first person as I did not consult any of my colleagues on the matter, believing that it was a matter of public duty to publish the letters at the earliest possible date. It falls to me personally, therefore, to make my humble apology.

JAMES CANTLIE.

MALARIA IN GREECE.—PROPOSALS FOR ANTI-MALARIAL MEASURES.

(Issued by the Liverpool School of Tropical Medicine.)

PROPOSAL FOR FIGHTING MALARIA IN GREECE.

DEAR SIR,—The Chairman and Committee of the Liverpool School of Tropical Medicine, in publishing the annexed appeal for subscriptions in aid of the Grecian Anti-Malaria League, wish to state:—

(1) That in reply to a telegram from the School, H.M. the King of Greece has signified his acceptance of any help that the School can give to the League of which he is the Patron.

(2) That H.R.H. Princess Christian, Honorary President of the School, has graciously consented to be the Patroness of the subscription in Great Britain.

(3) That Sir Francis Elliot, G.C.V.O., K.C.M.G., H.B.M., Minister at Athens, has kindly promised to receive the amount subscribed, and to hand it over to the Grecian Anti-Malaria League.

(4) That support to the scheme has already been promised by those whose names are printed in the accompanying list.

(5) That subscriptions may be paid to the Secretary, Liverpool School of Tropical Medicine, B10, Exchange Buildings, Liverpool.

ALFRED JONES,
Chairman, Liverpool School of Tropical Medicine.

The Liverpool School of Tropical Medicine, B10, Exchange Buildings, Liverpool.
July, 1906.

MALARIA IN GREECE.

By RONALD ROSS, C.B., F.R.S.

Professor of Tropical Medicine, University of Liverpool and Liverpool School of Tropical Medicine.

A LITTLE while ago I was asked by the Lake Kopais Company to make a study of the malaria which has long been prevalent on their estates in that part of Greece. Permission being granted by this University and School, I went there last May and carried out the required investigation. It revealed an unexpectedly high degree of malarial infection in most of the localities examined. Moreover, I ascertained from members of the Grecian Anti-Malaria League that the district of Kopais is by no means exceptional in this respect, and that the malady is very prevalent in many rural areas throughout the country. The League, which has existed for some years, has been doing its best to improve matters by modern methods, but is much hampered by lack of funds. After consideration, therefore, I have come to the conclusion that the case is one in which a little assistance from this country may do a great deal, and that we might well be justified in attempting to raise some small subscription among Greeks and other lovers of Greece resident in Britain, for the purpose of supporting so deserving a body.

Details regarding the prevalence of malaria in Greece are as follows: Professor Dr. Savas, Physician to H.M. the King of Greece and a Vice-President of the League, informed me that, taking the statistics of the larger towns for a basis (probably the lowest possible basis), the *average annual* number of cases must be something like 250,000, and deaths about 1,760. He said also, that malaria was particularly prevalent in Greece last year, the number of cases being perhaps half as numerous as the population.

From Dr. Kardamatis, General Secretary of the League, I obtained the following figures for last year:—

Estimated population of Greece ...	2,433,806
Estimated number of cases of malaria	960,048
Estimated deaths from malaria ...	5,916

It is always difficult to arrive at any exact estimate of the amount of malaria in any country; but these data appear to have been collected with all due care, and are certainly serious and startling enough for a European nation. It would appear that *in a single year*, there were roughly two attacks for every five persons in the country. Fortunately malaria, though

it is an extremely troublesome malady, is not often fatal; yet one in about every 410 persons seems to have died of it last year alone. I was informed also that blackwater fever, the most fatal form of the disease, often occurs in certain rural areas.

I will now describe my own experiences. It will be remembered that the Kopaic Lake was a large stretch of fresh water situated north-west of Bœotian Thebes at the feet of the slopes of Parnassus and Helikon. It was frequently drained by the ancients, and as frequently allowed to lapse again into the condition of a large marsh (in winter). Recently it has been kept well drained by the British Lake Kopais Company, the surface of the large plain so formed being used for extensive cultivation. On the margin of the plain there are a number of villages, some of which were examined by Dr. Kardamatis and myself, with the valuable assistance of Mr. D. Steele, agent of the Lake Kopais Company in Greece. The first method which we adopted for estimating the amount of malaria present was one which gives very reliable results when used with proper scientific precautions—namely, an examination of the people, chiefly the children, for enlargement of the spleen. Our general result was as follows: Out of 373 people examined enlargement of the spleen was observed in 96, or 23 per cent. But, in considering this ratio it must be remembered, first, that enlargement of the spleen is indicative, not only of a malarial infection, but generally of a long continued one; and, secondly, that the investigation was carried out in May and June, that is before the commencement of the annual autumnal malaria season. There is no doubt that an autumnal investigation would have disclosed a ratio of infection much higher even than this.

To give further details—at the village of Moulki, which is situated near the ancient Haliartos on the Kopaic Plain itself, we examined 80 persons and found enlargement of the spleen in no less than 38, or nearly half. At the village of Mazi, on the slopes of Helikon, just above Haliartos, we found it in 13 out of 40. At Skripou (the ancient Orchomenos) situated on the edge of the plain, it occurred in 25 out of 50 school children—exactly half. At the town of Livadhia, although it is at a distance from the Kopaic Plain and some way up the slope of Helikon, and is watered by running streams rising near the ancient Oracle of Trophonios, enlargement of the spleen was found in no less than 16 out of 100 school children. On the other hand, on the Kadmeia of Thebes, it occurred only in one out of 50 children.

Another method of estimating the amount of malaria present, namely, by searching preparations of the finger blood of the people for the parasites which cause the disease, need not be referred to here as the examinations are not yet complete; but so far as they have been carried they fully confirm the spleen-test, which of itself is sufficient for Greece. All the kinds of parasites have been readily found; and there can be no possible doubt regarding the wide prevalence of the disease. Many of the unfortunate little children, as they filed past us in the schools, presented a sad spectacle—pale and wizened, with enormously enlarged spleens and frequent attacks of fever. I have seen nothing worse in the most malarious parts of India; and nothing so bad in Africa, where there is probably more racial immunity. I suspect that there is a much larger infantile mortality in Greece than is shown by the statistics; and also that the adults, partially immunised as they are, cannot but lose in health and vigour in consequence of the unhealthy childhood which they must frequently pass through.

The question as to how far malaria has influenced the past history and the modern development of Greece, is one of the greatest interest, and will, I hope, receive future consideration. We must remember that nearly the whole surface of the country is mountainous, the arable tracts consisting of but a few small valleys or plains, maintaining most of the rural population. Yet it is precisely in these vital areas that the disease is most prevalent. True, some of the larger towns seem to be much less affected; but a nation can scarcely depend for its prosperity on its urban population alone. It is difficult to see how a vigorous country life can exist under the conditions which I have attempted to describe. One would expect to see many villages, churches, inns and country houses scattered about the landscape. The villages are few and poor, the country houses almost entirely absent. A gentleman in Athens told me that he bought a shooting box, but that when he went there he was immediately attacked by malaria. One would expect also to find plentiful accommodation for travellers all over a country where almost every hill, rock or stream is sacred to literature, art and history—which should be visited annually by thousands of tourists from all parts of the world. In reality we now see throughout these great valleys little more than what may almost be called scenes of desolation—bare hills, empty plains, a poor and scattered population.

Many years have passed since Byron gave his life for Greece. He attributed her misfortunes to loss of freedom. Is it possible that an enemy more inveterate than the Turk, has been really the cause of them? Looking at those poor children in the villages I feel inclined to think so.

Britain has done something for Greece in the past; and may now help her again, and perhaps in a more effective manner. Science has at length taught us how to combat malaria on a large scale. Ismailia, Havana, the Campagna, Hong Kong, Khartum, the Federated Malay States, give conclusive evidence of this; and so far as my own experiences teach me, the task in Greece will be a comparatively light one. Owing to the dryness of the climate and to the fact that the heavy rains fall in the winter, pools of water suitable for the propagation of the malaria-bearing gnats seem to be so small and isolated that they could easily, I think, be rendered uninhabitable for the insects; while the people are so intelligent that they are likely to accept readily enough the numerous other anti-malarial measures which may be adopted. Indeed, I will venture to say, that if the work is undertaken with the same degree of intelligence and persistence as was shown in the places just mentioned, the disease ought to be nearly banished from Greece in five years, and, moreover, at comparatively little cost. Such a result would be a most glorious victory, not of nation against nation, but of science against one of the principal enemies of mankind.

As I have said, the Anti-Malaria League of Greece, of which H.M. the King of Greece is Patron, has already commenced the battle, and I can testify has done so in a thoroughly practical and scientific manner. Its own duties are to indicate with exactness the sources of malaria near the principal towns and villages, to advise the Greek Government regarding the necessary measures, and to rouse the people to defend themselves by the simple precautions which are now so well known to medical men. All that we have to do—citizens or lovers of Greece in this country—is to try to help the League with funds and with sympathy. The former will enable it to do the necessary work; the latter will stimulate the Greeks themselves to aid in the task. With regard to the Government of H.M. the King of Greece, I can say confidently that we may fully rely upon its sympathy with the cause, and I say this, not as a mere compliment, but as the result of impressions gained by me during interviews with M. Theotokis, the Premier, and M. Boufidis, the President of the Chamber.

In conclusion, I can say with confidence that every penny spent in this cause is sure to give immediate and lasting benefit to Greece. For every tract distributed among the people, every pool of disease-breeding water drained away or filled up, there will be a corresponding saving of health and life; and, as the work progresses year by year, the hold of malaria on that beautiful country will be gradually relaxed until it is finally loosed altogether. The disease will disappear from Greece as it has disappeared from Britain.

Translation.

THE DISTRIBUTION OF BLOOD-SUCKING INSECTS IN WEST AFRICA.

By Dr. H. Ziemann.

The increase of the scientific and practical importance of the blood parasites, as regards tropical pathology, has also greatly augmented the interest taken in those animals which we know to propagate diseases of the blood. I am especially thinking of the great zeal shown in the collecting of Anopheles in all parts of the Tropics. Already in the years 1899, 1900, the writer of this paper endeavoured to collect the principal blood-sucking insects of Kamerun, Togo, and Liberia, and to urge further investigations in that direction.[1] But the untimely death of the zoologist, Müggenberg, unavoidably delayed the idea; in the meantime Theobald and Giles filled up the gaps in our knowledge of the *Culicidæ* of Africa.

In addition to the *Culicidæ* found in 1899, 1900, we are pleased to say that we also succeeded in demonstrating the presence of *Stegomyia fasciata* over wide areas; however, according to a letter received from Eysell, our species appears to differ from the specimens found in Habana. As is well known, *Stegomyia fasciata* is the transmitter of yellow fever. So far this disease has not been found in Kamerun, but once, in 1887, it was present on the west coast, and penetrated southward as far as Old Calabar, close to Kamerun.

Dr. Grünberg was able to distinguish the following species amongst the *Culicidæ* collected by me:—

(1) *Culex fatigans*, Wiedem.
(2) *Culex dissimilis*, Theob.
(3) *Culex masculus*, Theob.
(4) *Mansonia africana*.
(5) *Eretmapodites quinque costatus*, Theob.

Of these *Culex fatigans* is of importance as a probable transmitter of Filaria disease.[1] European Culices, such as *Culex pipiens* (which occurs also in Algeria); *C. nemorosus*, *C. annulatus*, &c., were not found.

Moreover, we succeeded in demonstrating the presence of piroplasmosis in animals[2] in all the domesticated animals of Kamerun, in the coast regions, and this disease may, in the case of native oxen of Kamerun, be distinguished from real Texas fever, viz., (1) by its comparative mildness; (2) by the lack of the typical pear-shaped forms of real Texas fever parasite, and (3) by the absence of hæmoglobinuria. The piroplasmosis of asses and cats, on the other hand, took a malignant course. Later, when out in South Africa, R. Koch also described, under the name of coast fever, a malignant piroplasmosis of oxen which has to be distinguished from real Texas fever. For this reason, earnest attention was paid to the *Ixodidæ*, in fact, to all parasites of mammals, and these were systematically collected. All stations have the duty to continue collecting and to send the material gathered to the State Hospital in Duala, which is the central station, for further use.

The difficulty of identification is very much enhanced by the fact that we may find on the same animals various species, and even different genera of *Ixodidæ*. Thus, for instance, I found on goats in Togo (Lome), *Rhipicephalus evertsi* (G. Neumann), and *Rhipicephalus simus* (C. L. Koch). I also found on oxen in Lagos, *Rhipicephalus annulatus* (Say) as well as *Ablyomma variegatum* (Fab.), on elephants in Kribi; *Dermacentor circumguttatus* (G. Neumann), and *Amblyomma tholloni* (G. Neumann). Further, in oxen in Lagos, *Hæmaphysalis parmata* (G. Neumann), and *Trichodectes sphærocephalus* (Nitzsch). It is true, this latter parasite does not belong to the *Ixodidæ*, but to the lice, but I mentioned it here for reasons of differential diagnosis.

We may be quite sure that, as investigation goes on, the frequency of the occurrence of different species of blood-sucking *Ixodidæ*, living on the same host, will increase. Generally speaking, it is certain that the species found in Upper Guinea differ slightly from those of Lower Guinea, but *Rhipicephalus annulatus* (Say) is the species which has the widest distribution. This tick is generally supposed to be the transmitter of the malaria of oxen (Texas fever). Next in order of frequency in Upper Guinea, is *Amblyomma variegatum*

[1] Ziemann. "Beitrag zur Anopheles-Fauna West Afrikas.," *Arch. f. Schiffs und Tropenhyg.*, 1902, Bd. vi.

[1] Ziemann: "The Filaria Disease in Man and Animal in the Tropics," *Deutsche Med. Wochenschr.*, 1905.

[2] Ziemann: "Preliminary Report on the Occurrence of Tsetse Disease in the Coast Regions of Kamerun"; "The Occurrence of Texas Fever in the Oxen of Kamerun, and More Information Concerning Tsetse Disease and Malaria of Animals," *Deutsche Med. Wochenschr.*, 1903, Nos. 15, 16.

to be found. It is very remarkable that I was also able to demonstrate the presence of *Amblyomma variegatum* on oxen in Bamenda, a mountainous highland, forming the hinterland of Kamerun. As a matter of fact the fauna of the further hinterland of Kamerun shows great similarity to that of Upper Guinea and the Western Soudan. In Lower Guinea, at any rate, in the coast region up to the foot of the mountains, the widest distributed genus seems to be a tick which has been named by Neumann, *Hæmophysalis parmata*. In addition to this species, Neumann found on the oxen of Kamerun a *Rhipicephalus ziemanni*. Its further zoological description I leave to Professor Neumann himself.

I think that we should draw up lists of all the parasites found in each colony, till finally, by having compared and interchanged the different lists of the different European colonies, we shall be able to get at the knowledge of the distribution of the principal blood-sucking parasites. The questions put to each single colonial district for the purpose of ascertaining the diseases of its animals, should in due time be answered, and these answers communicated to the other colonies.

Thus gradually we may hope to attain our purpose and to establish a comparative pathology of the animals in the African Tropics.

These were the reasons which prompted the writer to make also a collection of the flies which are known to transmit trypanosomes. Their identification has not yet been fully carried out. I will only remark in this connection that, according to Grünberg, *Glossina longipalpis* (Wied.) and *Glossina morsitans* (Westw.), transmitting, as we know, the Nagana disease, have not yet been found in the coast regions of Kamerun, though nevertheless the infection of the domestic animals by trypanosomes is very widely distributed. In Kamerun the following are known:—

(1) *Glossina palpalis* (Rob. Desv.), which is accused of carrying the trypanosome of sleeping sickness. (Found in several places, such as Victoria, Buea, Barombi, &c.) My own investigations lead me to believe that sleeping sickness on the coast only occurs sporadically, and even then it is imported; but it occurs more frequently in the hinterland. All imported cases therefore should be carefully isolated.

(2) *Glossina fusca* (Walk.), *seu tabaniformis*, Westwood, caught in the neighbourhood of the station Johann Albrechts Höhe (where there is also a trypanosomiasis of the domesticated animals).

(3) *Glossina tachinoides* (Westw.), from the Lake Tschad, which probably transmits a sort of tsetse-disease in the hinterland. Recently I received some blood films prepared from diseased animals, but they reached me in a useless condition.

Stomoxys and Tabanidæ, however, seem to be more widely distributed than the Glossinæ. The former constitute a veritable pest in some regions, as for instance in Mungo, especially *Chrysops dimidiatus* (van der Wulp). The domesticated animals in Duala harbour trypanosomes which may be distinguished clinically and morphologically from the Nagana parasites, and my observations tend to show that these Trypanosomes may be transmitted to the domestic animals by Stomoxys, or as is probably the case in Suellaba (Kamerun) by Tabanidæ. In the Philippines this seems to be the case as regards surra.

According to Grünberg it is possible that new species may be found amongst the Stomoxys and Tabanidæ sent from Kamerun.

The further biological investigations into the life habits and especially the breeding habits of these insects are therefore of the greatest possible importance, especially because we have to reckon on the possibility that the trypanosomes which are sucked up by the blood-sucking fly, together with the blood of the attacked animal, may be transmitted to the progeny of the insect in question. For further particulars on these practical and important questions we refer to Ziemann, "Beitrag zur Trypanosome infrage," *Centralblatt für Bakteriologie*, 1905, Heft 3, 4.

Review.

A Few Hints on the Care of Children at Sea. By Samuel Synge, M.A., M.D., M.A.O., B.Ch.(Dub. Univ.), L.M. London: J. Bale, Sons and Danielsson, Ltd., 83-91, Great Titchfield Street, W. Price 1s. net.

This excellent little book will become popular, and if it can be brought to the notice of passengers who have children in their charge will be universally sought after. Dr. Synge has really supplied what is often jocularly referred to as a long-felt want, but in this instance the legend is absolutely true. The "few hints," not only medicinally, but on every detail of child-life on board ship, are eminently practical, and show that the author has had experience of children at sea and has thought out carefully what is necessary in the way of preparation for the voyage and for application during the voyage. The "few hints" ought to be in the hands of every mother or nurse about to proceed to sea in charge of young children, for the instructions it contains will bring comfort to many an anxious and perplexed mother who has to proceed on a voyage with her infant child.

Correspondence.

PNEMONIC FOR THE SOLVENTS OF THYMOL.

To the Editors of the Journal of Tropical Medicine.

Sirs,—As the following pnemonic may prove as useful to others as it has to my dressers, I publish it in the interests of our tropical patients.

The solvents of thymol are of the greatest importance in the Tropics, where ankylostomiasis and other parasitic diseases of the intestinal tract exist in a far greater degree than at home.

The pnemonic is the word "Cottage (with one T)." The drugs represented by this word are: C, chloroform; O, oils; T, turpentine; A, alcohol; G, glycerine; E, ether.

There is no necessity for me to make any long statement on this subject, and I trust that others may profit in the comparative certainty of the non-occurrence of mistakes by the administration of solvents of this excellent drug to the same extent as I believe I have.

Notes and News.

MALIGNANT DISEASES IN CHINA.—Dr. J. Preston Maxwell, in practice at Eng-Chhun, Amoy, China, in his report of hospital work at Eng-Chhun in the *China Medical Missionary Journal*, May, 1906, states: "One of the features of the year's work has been the number of new growths which have come under treatment; certainly there is no lack of malignant disease in this region."

UNION MEDICAL COLLEGE, PEKING.—The Union Medical College was opened on the 14th of February, 1906. The professors and lecturers are drawn principally from the missions in the North China Educational Union and from co-operating missions. Chinese tutors are also included in the teaching staff.

The College has been established to provide well-educated Chinese with as thorough a knowledge as possible of the various branches of medicine and surgery. The degree of Doctor of Medicine will be conferred upon those students who succeed in passing the final examination.

The preliminary examinations are held in February in each year in the College. Candidates desiring to enter for the next college year should be in Peking before February 22nd, 1907, and should communicate with the Dean on their arrival.

The following are the members of the Faculty: Thomas Cochrane, M.B., C.M., Dean; Nehemiah S. Hopkins, M.D.; James H. Ingram, M.D.; George D. Lowry, M.A., M.D.; Charles Lewis, M.A., M.D.; Joseph F. Griggs, M.A., M.D.; Ernest J. Peill, M.B., Ch.B., F.R.C.S.(Edin.); Charles W. Young, B.S., M.D.; W. H. Graham Aspland, M.D., C.M., F.R.C.S. (Edin.), M.R.C.S., L.R.C.P.(Lond.), and thirteen other lecturers.

The medical course covers five years of nine months each. The year begins on or about the 20th of the Chinese first month and continues until the 20th of June; the autumn term begins on or about the 20th of September and continues until the Chinese New Year.

A CHINESE PRESCRIPTION.—Dr. W. H. Jeffreys, in an article in the *China Medical Missionary Journal* of May, 1906, gives the formula from a Chinese prescription for a cough. The prescription gives the patient's name, the diagnosis of the trouble, a statement of the condition of the pulse by which the diagnosis was made. The drugs are to be wrapped in a separate white paper and then altogether in a red sheet. The thirteen drugs are as follows: Baked barley, sugar, mashed beans, bamboo shavings, a root, another root, still another root, chalk, melon-seeds, mashed and fermented melon-seeds, a mashed pebble, some wild flowers, a broken clam shell. The ingredients are to be boiled together in a large quantity of water and drunk at one draught. Cicada shells is the great nervous sedative in China. Why the "sounding-board" of the scissors grinder (cicada) should be chosen is difficult to understand. In one respect, however, the Chinese concoction forms a pleasant contrast to European quack remedies, as it contains absolutely nothing that could possibly do any harm to the patient, and if there be any sound basis for hydropathy, the large quantity of water swallowed might possibly be beneficial.

THE Bombay Sanitary report shows a very heavy infantile mortality in the Presidency, 220 children *per mille* dying in their first year, while in the cities of Bombay and Ahmadabad the recorded figures give an infant mortality of 800 *per mille*, more than half the children born dying before they are a year old. The figures may not be particularly accurate, as registration in India is still very defective, but it is unlikely that more exact information would notably affect the proportional results.

LUDHIANA, an important city in the Punjab, is to have a modern water supply, and pipes, &c., to the amount of nearly £7,000 have been ordered from England.

ALTHOUGH diminishing somewhat in the native city, plague is increasing seriously in the cantonment of Poona, dead squirrels and rats having been found in nearly every house. An exceptional feature of the outbreak is the number of Europeans that have been attacked. The goods station master and his entire family have died and an officer of the Railway Survey Department has also fallen a victim to the disease. The deceased, it appears, picked up a squirrel which he erroneously thought to be dead, when the little animal turned round and bit him, with the result that within forty-eight hours he was removed to hospital in a dangerous condition. Government has sanctioned the expenditure of Rs. 500 on the purchase of Roux's serum, and Mr. Jacob Sassoon has given Rs. 1,000 for the same purpose.

AT the instance of the Sanitary Commissioner the Government of India have instituted a modified examination for promotion for native assistant surgeons employed in the Sanitary Department, special papers on hygiene, elementary bacteriology, &c., being substituted for those on surgery and midwifery. In the case of an assistant surgeon so employed, however, reverting to the ordinary line he will be expected to pass subsequently in the subjects excluded from the special examination. This may be considered the first step towards the formation of a specialist corps of medical subordinates, and is undoubtedly a most useful and promising innovation.

A MAN sleeping under a tree on the Calcutta Maidan, was attacked by hornets and so badly stung that he had to be removed to the College Hospital, where he died in a state of collapse half an hour after admission.

THE current number of the *British Medical Journal* includes a memorandum by Captain R. Markham Turner, I.M.S., of his discovery of the presence of a tsetse-fly in Arabia. The specimen has been identified by Mr. Newstead, of the Liverpool School of Tropical Medicine, as *Glossina tachinoides*, West-

wood. In view of the constant intercourse between Arabia and the African coast, the danger of the spread of sleeping sickness to the Asiatic continent is only too obvious, in view of this discovery.

Personal Notes.

INDIAN MEDICAL SERVICES.

Arrivals Reported in London.—None.

Extensions of Leave.—Lieutenant-Colonel A. Milne, 12 m. furlough; Major W. D. Sutherland, study leave, August 6th to October 10th, 1906; Major J. Chaylor White, 1 m. medical certificate; Captain F. A. Smith, study leave, September 1st to September 30th, 1906; Captain L. P. Stephen, 2 days.

Permitted to Return to Duty.—Captain N. R. J. Ranier, Major J. Chaytor White, Captain R. E. Lloyd, Lieutenant-Colonel A. C. Younan, Captain L. P. Stephen, Lieutenant G. F. T. Harkness.

Postings.

Captain R. F. Baird officiates as Deputy Sanitary Commissioner, 1st Circle, United Provinces.

Captain E. S. Morgan, on return from leave to be Civil Surgeon, Etawah.

Captain O. Dykes officiates as Civil Surgeon, Jaunpur.

Captain Melville to be Professor of Materia Medica, Lahore Medical College.

Captain M. Mackelvie and E. H. B. Stanley, services lent to Civil Department, Bengal.

Captain J. W. Little, Civil Surgeon, Wano, is transferred to Gwalior as Residency Surgeon, his place being taken by Captain J. R. Tyrrell, now on famine duty in Rajputana.

Major M. H. W. Hayward, services placed at disposal Government of Bengal.

Lieutenant-Colonel J. Sykes, Civil Surgeon, on return from leave, to Bareilly.

Lieutenant-Colonel J. Jarratt, Civil Surgeon, on return from leave, to Fyzabad.

Major H. Austen-Smith, Civil Surgeon, on return from leave, to Bahraich.

Captain W. B. Turnbull, Officiating Civil Surgeon on return from leave, to Banda.

Major W. Selby, Civil Surgeon, from Bareilly to Sitapur.

Major C. Milne, Civil Surgeon, from Fyzabad to Gonda.

Civil Surgeon Man Mohan Das, on being relieved, from Bahraich to Hamirpur.

Military Assistant Surgeon W. J. A. Hogan, Civil Surgeon, on being relieved, from Banda to Pilibhit.

Lieutenant-Colonel J. A. Cunningham to be Civil Surgeon, Umballa.

Leave.

Major Melville, furlough for 1 year.

Captain V. G. N. Stokes, combined leave for 1 year.

Retirements.

Honorary Captain C. Gill, I.S.M.D.

R.A.M.C.

Lieutenant-Colonel A. E. Morris to Command Station Hospital, Jubbulpur; Major F. R. Buswell, to that of Jubbulpur; Captain F. Kiddle to that of Abu; Captain A. R. O'Flaherty to that of Sangor; and Captain D. O. Hyde to that of Khandalla; Lieutenant-Colonel H. A. Haines officiates in command, Station Hospital, Umballa; Lieutenant-Colonel T. P. Woodhouse officiates as P.M.O., Lahore division.

"Medizinische Blätter," No. 10, 1906.

ANKYLOSTOMES AN ETIOLOGICAL FACTOR IN MALARIA.

Sehrwald, of Brazil, states that he finds in persons suffering from malaria and infected by *Ankylostomum duodenale* that these worms contain the malarial parasite in their intestine and in the mucous glands of the ankylostome's mouth. Sehrwald is of opinion that these parasites may directly reinfect man, and may transmit malaria by means of eggs or larvæ. It is necessary in such cases to cause the expulsion of the worms before treating the anæmia present in all patients thus afflicted.

Recent and Current Literature.

A tabulated list of recent publications and articles bearing on tropical diseases is given below. To readers interested in any branch of tropical literature mentioned in these lists the Editors of the JOURNAL OF TROPICAL MEDICINE *will be pleased, when possible, to send, on application, the medical journals in which the articles appear.*

"Annual Report of Government Veterinary Bacteriologist," Pretoria, 1906, p. 110.

"BLUETONGUE" IN SHEEP.

Theiler, A. The disease may be met with throughout the Transvaal in marshy localities and along the river banks, and is especially rife in the autumn, *i.e.*, in the rainy season, and it is very probable that, like "horse sickness," it may be conveyed by a nocturnal biting insect. As the blood of the sheep that have suffered from the malady ceases to be virulent after recovery, it may be supposed that during the dry season the virus is preserved either in the intermediate host, or in the body of some vertebrate other than the sheep, possibly aquatic.

The virus contained in the blood or serum, if well diluted with physiological water, passes through a Berkefeld filter. The dried blood dissolved in physiological water, and inoculated, produces, after the usual period of incubation, a characteristic febrile reaction, and it is possible that this may be made the basis of a plan of vaccination.

The immunity conferred by a single inoculation is, however, somewhat feeble, and further inoculations of increasing doses are usually followed by the symptoms of bluetongue and sometimes by death. Sometimes, however, immunity is acquired after a second inoculation of blood, as was also found by Spreull, and Theiler further confirms that observer's statement, that sheep which have passed through the disease, and have afterwards been injected with 500 cc. of virulent blood, yield a serum which possesses preventive properties, 5 to 10 cc. of such serum suffice to protect, but do not cause any obvious reaction.

"Bulletin de l'Académie de Médecine," Paris, Year lxx., Nos. 8, 9.

ANTI-DYSENTERIC SERUM.

Vaillard, L., and Dopter, C., immunised horses by inoculation on alternate weeks with progressive doses of living bacilli and of soluble toxin. The toxin is obtained by filtering through porcelain a culture of dysenteric bacillus in Martin bouillon kept for twenty days at a temperature of 37° C. of ninety-six patients treated by hypodermic injections, and later by injections into veins; all recovered except one. Of the patients thus treated, all had been subjected to the usual dysenteric remedies unsuccessfully. As soon as the serum treated was employed, the patients' condition altered for the better, and recovery was established in from two to six days, according to severity of illness. No untoward symptoms are reported from the serum treated. The minimum dose employed was 20 cc. hypodermically given and repeated once or twice in the severer cases.

Notices to Correspondents.

1.—Manuscripts sent in cannot be returned.

2.—As our contributors are for the most part resident abroad, proofs will not be submitted to those dwelling outside the United Kingdom, unless specially desired and arranged for.

3.—To ensure accuracy in printing it is specially requested that all communications should be written clearly.

4.—Authors desiring reprints of their communications to the JOURNAL OF TROPICAL MEDICINE should communicate with the Publishers.

5.—Correspondents should look for replies under the heading "Answers to Correspondents."

Original Communication.

HUMAN SPIRILLOSIS IN LOANDA (ANGOLA).

By A. de S. Maia Leitao, M.D. (Oporto).

Captain Portuguese Colonial Medical Service; formerly at London School of Tropical Medicine.

(Preliminary Note.)

(Translated by the author from the note sent to the "Archivos de Hygiene e Pathologia Exoticas," of Lisbon.)

On July 24th, 1906, on examining the blood of a black soldier, native of Golungo, aged 24, who has been in service in Loanda some time, I found spirilla like those of Obermeieri [1].

The blood of the patient was examined by the writer at the request of Clinical Assistant Dr. G. Vicira, of the "Hospital Maria Pia," of Loanda, who suspected trypanosomiasis.

The blood films were stained by Leishman's stain, and examined by the $\frac{1}{12}$ oil immersion lens, when they showed the spirilla referred to.

It is the first time, to my knowledge, that this disease has been found in Loanda, and I therefore hasten to communicate the fact, although I have deferred making it public for some time, hoping to find other cases of the disease and also to find the tick [2] — *Ornithodoros moubata* — which is reported to be present in Loanda, but I have failed to find it up to the present.

I am also looking for the enemy of this tick—the *reduviidius* of F. C. Wellman, M.D., which was classified by E. E. Austen as *Phonergates bicoloripes*, Stål [3].

When the patient entered the hospital he was in the last stages of the disease, so that only the first blood examination was positive, and owing to the subsequent examinations being negative I could not make inoculations of animals.

Later the embryos of *Filaria perstans* were found in the blood of the same patient. As soon as further opportunity affords I will endeavour to ascertain whether this spirillum is *Spirillum Obermeieri* or *S. Duttoni*, or whether it differs in any way from these two. For this purpose I shall adopt pretty closely the views of Frederick G. Novy and R. E. Knapp [4].

References.

[1] I have sent blood films to the London and Lisbon Schools of Tropical Medicine to be verified.

[2] The Portuguese name is "Carrapato" not "Garrapato," as Sir Patrick Manson has it in his "Tropical Diseases," p. 714, 3rd edition, 1903.

Business Notices.

1.—The address of the Journal of Tropical Medicine is Messrs. Bale, Sons & Danielsson, Ltd., 83-91, Great Titchfield Street, London, W.

2.—All **literary communications** should be addressed **to the Editors.**

3.—All **business communications** and **payments,** either for subscriptions or advertisements, should be sent **to the Publishers** of the Journal of Tropical Medicine. Cheques to be crossed The Union Bank of London, Ltd.

4.—The Subscription, which is **Eighteen Shillings** per annum, may commence at any time, and is payable in advance.

5.—Change of address should be promptly notified.

6.—Non-receipt of copies of the Journal should be notified to the Publishers.

7.—The Journal will be issued on the first and fifteenth day of every month.

Reprints.

Contributors of Original Articles will be supplied free with six copies of the Journal if a request accompany the MS. If reprints are required they will be supplied by the publishers, if the order is given with remittance when sending the MS. The price will be as below:—

50	Copies of four pages,		5/-;
100	,,	,,	6/-;
200	,,	,,	7/6;
50	Copies beyond four up to eight pages,		8/6;
100	,,	,,	11/-;
200	,,	,,	14/6.

One page of the Journal equals 3 pp. of the reprint.

If a printed cover is desired the extra cost will be for 50 Copies, 5/6; 100 Copies, 6/6; 200 Copies, 7/6.

THE

Journal of Tropical Medicine

December 1, 1906.

THE AFRICAN POISON TEST.

Dr. F. C. Wellman, in an article published under the *imprimata* of the American Society of Tropical Medicine, gives an interesting account of the African poison test as observed in the Portuguese colony of Angola, West Africa. The test by poison is employed as a means of settling disputes in many parts of Africa, and from time to time we have accounts which give so varied statements of the method, ritual, and drugs employed that many untravelled people regard the reports as mere travellers' tales.

Dr. Wellman's account is taken from observations amongst the Umbundu-speaking Bantus in the province of Angola, and he describes the poison test as it is practised amongst these people. Ombulungu is the local name for the ordeal, which, however, has different names in different parts of Africa.

The custom of administering justice by the poison test is of ancient origin, but has come down to the present day with an accumulation of ritual and ceremonial which tend to obscure the rational and elevate the mythical phase of the proceeding. The poison test is appealed to on occasions of disputes of several kinds, and withal so frequently that, according to Dr. Wellman, it is "a custom which has nearly depopulated whole districts, and has been responsible

for more deaths in Africa than have many important diseases."

The disputes which occasion resort to the poison test are: Hereditary disputes—family or clan feuds in fact; cases of murder when there is doubt as to the culprit; cases of adultery, and cases of alleged killing by witchcraft. In addition to these causes of quarrel, acts of thieving, be it of stolen property, slaves, wives, or cattle, after settlement by divination in presence of a witch doctor is impossible, the aggrieved party challenges his antagonist to trial by poison. To refuse the challenge is equivalent to a confession of guilt. When the quarrel reaches this point a witch doctor acceptable to both parties in the quarrel is decided upon, and with him lies the duty of preparing the poison. To the witch doctor each party to the quarrel, accompanied by friends and relatives, proceeds, and after preliminary speeches by the combatants, in which each loudly asserts his innocence, the poison is given them to drink. After drinking, a native dance takes place, and whichever man first falls down is held to be the guilty party. His friends then carry him away to die or recover, according to the strength of the poison given him.

There seems a certain rude justice in this account of the poison test, but when we come to look below the surface we find that, the witch doctor not being above bribery, it is usually the litigant with the longest purse that wins. "Refreshers" in the form of presents serve to bribe the judge, and to warp his mind so that his decision is settled beforehand, and the method and manner of administering the poison draught is tampered with accordingly.

Dr. Wellman points out some of the tricks by which the witch doctor adjusts the draught in accordance with his preconceived conclusions as to which of the litigants is to die. One plan is to fill two drinking vessels (*gourds*) with apparently similar ingredients, one for each of the disputants; but although to all appearances identical, one of the vessels, that intended for the unfortunate man whom it is meant to condemn, contains a potent poison. Another plan is, however, more subtle; one *gourd* only is used, the favoured individual is given the first half of the draught to drink, his opponent the latter half. After the former has finished his draught, however, the contents of the vessel are stirred, whereby the actual poison, which hitherto lay at the bottom, is mixed with the fluid, when the second man receives the full benefit of the lethal substance. Several other methods of trickery are practised by the witch doctor, such as enclosing the poison in a resinous substance placed at the bottom of the vessel, which can be liberated when desired by scratching the resinous enclosure with the nail of the finger when stirring the decoction. Instead of this, a skin bag with two compartments, one containing a poisonous, the other an innocuous, powder of similar colour is employed, and the contents of either bag dusted in the fluid into the *gourd* as desired.

Dr. Wellman gives the plants from which the substances used in the poison test are obtained in various parts of Africa with his customary accuracy of detail. Of these he mentioned *Strychnos icaja* (Baill.); *Physostigma venosum* (Balf.); *Erythroplæum judicale* (Proct.); *Tanghinia venenifera* (Poir.); *Allenium somalense* (Poir.); and *Menabea venenata* (Baill.).

Amongst the Umbundus, however, none of the above were used, but instead *Erythroplæum* (*E. guineense*) (Don.), with two other poisonous plants, namely, *Securidaca longipedunculata* (Fres.) — the Utica bush, and more rarely *Tephrosia vogelii* (Hook, *fil*).

The effect of the mixture used in the poison test by the Umbundus is, in the first onset of symptoms, vomiting and purging. This is followed later by loss of power in the limbs, and the victim falls to the ground and dies speedily and quietly. The administration of the test occasionally fails owing to the witch doctor's inefficient steps in mixing or disguising the poison, when both disputants may die from the effects of the draught.

THE ORGANISATION OF THE MEDICAL SERVICE OF THE NATIVE ARMY OF INDIA.

The organisation of the military section of Indian Medical Service has during the last few weeks formed the subject of two leading articles in an influential Indian contemporary, the *Pioneer*, and as that journal usually keeps itself well in touch with the official hierarchy of Simla, it may be taken as tolerably certain that the subject would not receive such marked attention in its columns unless changes of organisation were under consideration.

The present system, it may be admitted, is somewhat archaic, being simply the old and somewhat discredited "regimental system," but it by no means follows that it is therefore unsuited to the Indian Army, as it must be remembered that Indian civilisation is also very archaic, and although the sepoy is armed and drilled on the most approved modern European models, he remains in his social and domestic life a very archaic person. Soldiers' institutes and sergeants' messes, athletic clubs, and so forth, have, for example, become absolute necessities of life for the British soldier, but they would be impossible and useless in the native army; and the same differences of habits that make our European organisation of the social side of military life unsuited to native troops, deprives the station hospital system of most of its advantages when applied to them. Perhaps the most striking advantage that can be claimed for the station hospital system is the greater efficiency and economy of dieting arrangements, but owing to caste prejudices nothing of the kind can be attempted on behalf of the native, as some castes are so exclusive as to object to take food even if prepared by a Brahman of the highest standing. It is extremely difficult to convey to the uninitiated the difficulties that meet the European physician at every point of the dieting and nursing of native patients, and as our native regiments are almost universally recruited from men of the best and most exclusive castes, a vast amount of tact and an intimate knowledge of caste custom are essential to the medical officer of a native corps to enable him to exercise his profession with success. Moreover, the subdivisions of caste are so

intricate, and the tendency to fission within the caste is so strong, that it by no means follows that one can prudently act in the case of the 100th Dogras in the same way as one might in the 101st of the same caste. The redeeming point of the old regimental system in the British service was the personal knowledge of his patients acquired by the regimental medical officer, a most valuable asset to any physician, but the importance of such knowledge for him is but trivial as compared with its indispensable character in the case of native troops.

The weakness of the regimental system lies, of course, in its inapplicability to modern conditions of active service.

The *Pioneer*, it must be remembered, unlike our European lay journals, appeals mainly to an official public, and to a great extent may be said to be written by experts for experts, and it may be well, therefore, to consider seriously the line of argument taken by it, and the proposals it has to make for improvement.

It takes as its text an excellent remark of Colonel P. S. Maitland, in a paper on Army Re-organisation, read before the United Service Institution of India in 1890, which runs as follows:—

"There is one condition that is universally recognised in the organisation of the army of every State which has any pretensions to rank as a military Power, and also in some which have no pretensions at all. It is, I think, not too much to say that this condition exists in every army whose efficiency is of vital importance to its country, and it may therefore be regarded as an essential factor in producing that efficiency. This condition is that the war organisation of an army is precisely the same as the peace organisation. What I mean to say is that the army corps, divisions, brigades of an army with their staffs, trains and subsidiary organisations, exist in peace as they do in the field."

Judged by this indisputable test, it is at once seen that the station hospital plan stands under even deeper condemnation than the regimental system, for while the latter serves very well for short operations in which only small numbers of troops are employed, such as the counter raids on the frontier that are unfortunately so often unavoidable in India; the station hospital system has to be replaced on service by an elaborate system of field hospitals, in the working of which the officer has had no practice whatever during peace.

With the scathing condemnation of the station hospital system indulged in by our contemporary we have little sympathy, for while we equally regard the plan as a bad one in principle, we know that the skill and devotion of the officers of the R.A.M.C. have made it, practically speaking, extremely efficient for all that it is fit for—the necessities, to wit, of peace time. What we regard as its most striking defect is the lack of opportunities of exercising responsibility for the junior officer, as the latter is little more than a sort of superior clinical clerk to the senior medical officer, and so acquires practically no experience of the responsibilities of charge until, after long years, he has them thrown by seniority on his quite unaccustomed shoulders.

The regimental system, however, has this marked advantage, that the habit and practice of responsible charge is thrown on the medical officer from almost the very outset of his service, and it is probably owing to this, more than to any other cause, that in spite of its admitted defects, our Indian medical military organisation has always "worried through" without an actual breakdown.

The *Pioneer*, therefore, proposes to retain the regimental system, but to institute an addition—a system of field and general hospitals, attached—which is most important—not to stations but to brigades. The regimental officer would attend to the sanitary necessities of his corps and provide for its military surgical arrangements as a unit in action, and would attend to the trivial cases in peace time, passing on the more serious cases to the field or general hospital just as he would in war, but the officers of the latter would form an integral part of the Brigade to which they belonged, and so would retain the personal touch with their patients, so essential in dealing with native troops.

It is obvious that when the regimental work in peace time was too light to occupy the entire time of an officer, his services might be utilised to some extent in the larger hospital by giving him a ward, for the *medical* treatment within which he should be solely responsible, and also that under such a plan all that would be required on a Brigade taking the field would be, as our contemporary remarks, not "alteration, but expansion," by the strengthening of the field hospitals by additions to their staffs, as it is obvious that on active service the regimental surgeon, forming as he would this first line of medical aid, could not be made in any way available for assistance in the second and third lines. Space forbids our entering into the details of the plan as outlined by our contemporary, but there is undoubtedly much to be said in its favour, and we therefore trust that the article referred to may really be taken as a shadow forecast by the events that are being worked towards by the responsible authorities.

It is obvious, however, that, like most changes tending to increase efficiency, the plan so ably advocated by the *Pioneer* involves a considerable increased expenditure. The regimental medical officer remains as such, and a considerable addition must be made to the nominal roll of the service, to afford at least the nucleus of a *personnel* for the field and general hospitals. The station hospital plan, on the other hand, though nasty, is cheap; cheaper even, perhaps, than the regimental system, though the latter is extremely inexpensive as worked in the native army, where practically one commissioned officer and two or three subordinates (hospital assistants and compounders) for each battalion, with a few odd men thrown in for staff and detachment work, form the entire *personnel*. This proportion of medical aid to fighting men is, of course, far smaller than that subsisting in the British Army under the station hospital plan, and it is extremely doubtful if even in the native army the latter could be worked with a smaller personnel than that now employed, under the regimental system.

It must be remembered that the Indian Medical Service enjoys an advantage possessed by no other military medical organisation in the shape of a reserve

of trained military surgeons much stronger in number than those actually employed with the troops.

This reserve is the Civil Branch. When war breaks out the civil surgeons hand over their duties to their native assistant surgeons, who are fully qualified practitioners, and at once proceed to the front, when in practice they officer the field and general hospitals, the regimental officers naturally and justly claiming the more attractive share of the work in accompanying the fighting line. Having all passed through a more or less prolonged period of military work and being habituated to constant and onerous administrative responsibility, they fall naturally and easily into their places, and the practical outcome of the present system is very much the same as the theoretically more ideal system advocated by the *Pioneer*.

During the Tirah Campaign, for example, something like a third of the civil surgeons in the United Provinces were withdrawn for service in the field. And really all that is wanted to secure smooth working is occasional mobilisation operations in time of peace; so that whenever manœuvres were conducted within their Province, the civil surgeons might occasionally enjoy the opportunity of mobilising their field hospitals, the materials of which might be stored at provincial capitals under the charge of the regimental officers stationed there. Failing, therefore, the funds to carry into effect the more ideal system advocated by the *Pioneer*, why not leave things alone?

EXPERIMENTS IN PRACTICAL CULICIDAL FUMIGATION.

Arthur I. Kendall, Ph.D., of the Board of Health Laboratory, Panama, states that one of the most important sanitary problems associated with the digging of the Panama Canal is the suppression of mosquito-borne diseases. The destruction of mosquitoes is accomplished in several ways, but Mr. Kendall deals only with fumigation.

Methods of Procedure.

(1) Preparation of the house: Disturb the apartments as little as possible; stop up all openings; have the door guarded by a canvas curtain.

(2) To fumigate: For each 1,000 cubic feet of air space, 2 lbs. of sulphur, or 2 lbs. to 4 lbs. pyrethrum, are placed in a pot and set alight.

(3) After a few hours the house is opened up, the mosquitoes swept up with a damp broom, the paper and paste used in stopping up cracks removed. Of the several fumigants, sulphur is the most convenient for use. Pyrethrum, also known under the names of "Bubach," Persian insect powder and Dalmatian powder, is used, but the powder should be that obtained from unexpanded flowers, and not the adulterated varieties frequently offered for sale.

Campho-phenique, called also Mimm's mixture, consists of a mixture of equal weights of camphor and (95 per cent.) carbolic acid, and has proved a fairly reliable culicide. Four ounces of the mixture is placed on shallow pans for each 1,000 cubic feet of air space, and subjected to the heat of an alcohol lamp.

Of the three fumigants mentioned, campho-phenique has the advantage of being cheap, efficient and non-objectionable. Sulphur is efficient but proves injurious to fittings and fabrics. Pyrethrum is unreliable and causes darkening of light-coloured paint and similar substances.

Several other fumigants have been experimented with. Concerning these it is stated: Hydrocyanic acid is dangerous to human beings, owing to its poisonous fumes; chlorine gas has the disadvantage of bleeching fabrics; carbon disulphide is dangerous owing to its inflammability; Jimson weed or stramonium is unreliable; formaldehyde is an unsatisfactory insecticide, although so potent a bactericide.

JUVENILE SMOKING.

It is said that we are without information as to the effects of smoking upon native children in warm climates. Our correspondents might help the enquiry now being conducted by a Select Committee of the House of Lords, which is at present engaged upon the Juvenile Smoking Bill, by giving their opinions. We do not ask for scientific proofs concerning the effects of smoking on native children, that is well-nigh impossible, but although definite proofs may be wanting, observations on the subject may be of value.

The points we suggest for enquiry and reply are:—

(1) Do the children of natives in warm climates commence to smoke at a very early age, and, if so, state approximately at what age?

(2) Are deleterious effects observable?

(3) What is the form in which tobacco is used?

(4) Do parents in the Tropics discourage the use of tobacco by their children?

(5) Are parents of opinion that juvenile smoking is deleterious, if so, in what way?

(6) Is tobacco supposed to have any beneficial action in the prevention of disease?

Answers to these questions, forwarded to the Editors, will be submitted to the Select Committee of the House of Lords.

PRECISE DEFINITION OF DISEASES.

Dr. James F. Leys, Surgeon United States Navy, in an article which appeared in the *Medical Record* of June 10th, 1906, draws attention to the nature of the definitions customary in medical text-books. He objects, and rightly, too, to the use of *a* or *an* in defining specific diseases, and cites as an example a so-called definition of anthrax commencing, "Anthrax is *an* acute," &c. Leys would employ the following formula for a disease of which the cause is known: Anthrax is "*the* disease caused by an invasion of *Bacillus anthracis*." In the same way actinomycosis is *the* disease caused by an invasion of *Actinomyces bovis*. Similarly may be defined tuberculosis, diph-

theria, malaria, and so on through all the diseases the cause of which is known. It is to be hoped Dr. Ley's advice will be taken, and so-called definitions, which are more in the nature of short descriptions, at present in use be dropped.

ANTI-MALARIAL CAMPAIGN IN AUSTRIA AND HUNGARY.

THE Austrian Government has during the past two years been conducting an anti-malarial campaign along the Adriatic coast with marked success. It is from this region that the majority of sailors for the fleet are recruited, and the prevalence of malaria amongst the inhabitants of the coast has proved a serious detriment to the health of the navy. The means taken to eradicate the disease is by draining swampy grounds, oiling collections of water, and the distribution of quinine. The success of these measures has been proved by the fact that during the past two years the number of fresh cases of malaria declined 62 per cent. The Governor of Dalmatia has instituted similar prophylactic measures in his province with encouraging success. In Hungary, the part played by the mosquito in the spread of malaria is being taught, and in many districts stringent measures are being prosecuted to exterminate the Anopheles.

Reports.

MEDICAL OFFICERS OF MISSIONARY SOCIETIES' ASSOCIATION.

AT meetings of this Society held in May and October, Mr. McAdam Eccles introduced the subject of "The Surgical Aspect of the Missionary Candidate"; he dealt with the various systems *seriatim*, the following being an epitome:—

RESPIRATORY SYSTEM.

Allusions were made to deflected septum of the nose and to nasal polypi, and to *adenoids* and their consequences. He said that many a missionary candidate had poor physique owing to the results of adenoids, and to a town life, particularly when their occupation had been that of clerk or shop-woman. It was important to see that there was no defect of the larynx, as a clear voice was of much importance in the preacher.

ALIMENTARY SYSTEM.

With regard to the question of teeth, the first fact of importance was whether the loss of a certain number of teeth negatived the going abroad of the candidate. Mr. Eccles thought not, but that the question of how the teeth met, in other words, their usefulness, was the real issue. Artificial teeth were essential for those who had lost a number of teeth, but they must be good, simple, worn for some time previous to leaving England, and two sets should be taken out.

Should a *hernia* disqualify? Mr. Eccles answered this in the positive. A radical operation should be performed at least six months before going out. Femoral herniæ, and particularly those in men, were more dangerous than inguinal, and possibly umbilical even more than femoral.

What should be the course adopted with regard to *appendicitis?* He was emphatic that if there has been one attack of a definite nature, operation was imperative before the candidate could be allowed to proceed abroad.

VASCULAR SYSTEM.

Varicose veins, should they be always a bar to service? No, it depends upon the variety of varicosity. There are really three forms of varicose veins, one the single enlarged vein, due probably to a congenital defect, and one easily cured by operation; the second, the congestive form, in which there are a number of small superficial veins enlarged, these give rise to much trouble and are difficult to cure by operation, and probably it is best to reject the candidate who is the possessor of them; the third form, due to obstruction by pressure within the abdomen, means, as a rule, that there is trouble which necessitates rejection, unless the pressure can be satisfactorily removed, and that permanently.

Varicocele.—Here, again, each case has to be taken on its merits. Slight enlargement of the spermatic veins, especially if there have been no symptoms arising therefrom, need not be dealt with surgically, and it is important not to draw the candidate's attention to them, if he does not complain of them. On the other hand, if there has been trouble from these varicose veins, it may be that this very fact is an indication that the person is not a suitable one to stand the wear and tear of a life in tropical climes.

Hæmorrhoids.—These should always be operated upon, on account of the increased liability to constipation on foreign service. Also returned missionaries who have been subject to hæmorrhoids should be strongly advised to have them treated surgically.

LYMPHATIC SYSTEM.

Enlarged Glands.—These often mean that the candidate has had poor physique, and scars in the neck should always mean a careful examination. It has been suggested that tuberculous glands in early life tend to render the person immune to tubercle in later years; this may be so, but there is often an inherent weakness in persons who have been the subject of tuberculous glands.

Enlarged Thyroid Gland.—This is not necessarily a bar to work in the foreign field, but great care should be taken to exclude the candidate should the enlargement be the indication of early exophthalmic goitre.

LOCOMOTORY SYSTEM.

There are a large number of conditions of the feet which, although apparently small in themselves, are of great importance from the point of view of the missionary candidate.

Flat-foot.—Any tendency to flat feet, particularly in women, should be looked upon with suspicion, often indicating general want of tone.

"*In-growing Toe-nail.*"—It is well to bear in mind that this condition is very common, and that it is not due to the "in-growing" of the nail, but to the over-pushing of the soft parts. The treatment of the lesion is not to remove the great-toe-nail, but to push back the soft parts, and to see that a proper boot is worn.

Hammer-Toe. — This condition may cause most troublesome lameness, and should be treated surgically before a candidate is accepted.

Hallux Valgus. — The same applies to this deformity.

Diseases of Joints.—There are several lesions of joints which naturally interfere with locomotion, and may be of hindrance to the missionary. They may necessitate the refusal of the candidate. Loose bodies and loose cartilages should be treated by operation before the possessor proceeds abroad.

Paralysis, including Infantile Paralysis.—It is probably best to refuse a candidate who is the subject of paralysis of any kind.

Deformities.—Any marked deformity is a contra-indication to acceptance.

Special Senses.

Eyes.—The importance of eye symptoms cannot be over-rated. Headaches, mental strain, and other conditions are often due to eye lesions, and any tendency to these should lead to a careful examination of the eyes. If it is necessary for spectacles to be worn, they should be fitted and tested some months before the missionary goes abroad, and a spare duplicate instrument should always be taken out.

Ears.—Otitis media, if present, should always disqualify, and any great degree of deafness would also do the same.

Discussion was adjourned till the Association's meeting on October 30th, when, amongst others, the following members took part: Colonel Hendley, I.M.S., Mrs. Scharlieb, M.D., Drs. MacDonald, Harford, Soltau, Fox, and Price. Discussion centred chiefly round the questions whether with an indefinite history of an attack of appendicitis an operation should be performed? Whether the operation, having been successful, the individual was by the nature of the disease predisposed to enteric infection? Cases being quoted to support such an hypothesis.

The question of enlarged glands, which had suppurated earlier in life, leaving behind merely scars, proved also of interest, particularly with regard to the problem whether in such cases there was immunity from tubercle conferred, or whether such individual under the stress and strain of life abroad showed an increased incidence of tuberculous disease.

The condition of movable kidney in the candidate was also brought forward.

THE SOUTH AFRICAN MEDICAL CONGRESS.

On October 1st, 1906, the South African Medical Congress was opened at Bloemfontein, Orange River Colony. Some seventy medical men from widely separated parts of South Africa were present. The Hon. F. Wilson, C.M.G., acting Lieutenant-Governor of the Orange River Colony, opened the Congress, and in the course of his speech dealt with the various laws affecting medical men and the public health. The President of the Congress, A. E. W. Ramsbottom, M.D., of Bloemfontein, in his opening address, strongly advocated unity amongst medical men in South Africa.

The President of the Section of Medicine, H. Aylmer Dumat, M.D.Edin., F.R.C.P.Edin., delivered an address entitled, "The Motive Powers of the Mind." G. Porter Mathew, M.D., opened the discussion on "The Treatment of Uterine Displacements." Drs. Klots, Murray, Mackenzie, Davies, Ashe, Gordon, Grant, and Knobel took part in the discussion.

G. Ritchie Thomson, M.B., C.M.Edin., F.R.S. Edin., read a paper entitled, "The Diagnosis and Treatment of Diseases of the Biliary Passages." Drs. Ashe, Davies, Knobel, Murray, and Richardson discussed the paper.

G. E. Murray, M.B., F.R.C.S., read a paper on "Fistulous Communications with the Urinary Tract."

J. B. Knobel, M.D., L.R.C.S.Edin., contributed a paper on "A Case of Obstinate Ulceration of the Dorsum of the Fingers and Dorsum of the Left Hand, probably due to Unilateral Raynaud's Disease."

His Excellency the Acting Governor of the Orange River Colony attended the Public Health Section of the Congress, and took part in the work of the Section.

Miscellaneous.

PIETRO JAMES MICHELLI, C.M.G.

(Secretary Seamen's Hospital, and London School of Tropical Medicine.)

The authorities of the London School of Tropical Medicine are well aware of their indebtedness to Mr. Michelli, upon whom His Majesty King Edward VII. recently bestowed the most honourable distinction of Companion of St. Michael and St. George. It may be safely said that the honour has never been bestowed upon one more worthy of the distinction. The London School of Tropical Medicine has been built up, launched, floated, and started upon its useful and successful mission under Mr. Michelli's capable and efficient pilotage; and it is to be hoped he may continue for many years to shape its course and stand by its helm.

It was to Mr. Michelli that Sir Patrick Manson, in 1897, first unfolded his scheme for imparting instruction in tropical medicine, and from that date until the present moment Mr. Michelli has taken a lively and enthusiastic interest in all that appertained to the success of the School.

The scheme once formulated was submitted to the Board of Management of the Seamen's Hospital Society. The members of the Board grasped the national importance of the proposal. The then Deputy

Chairman (now the Chairman of the Board), Mr. Perceval A. Nairne, entered heartily into the development of a school of the kind, and, loyally assisted by his colleagues, they resolved to finance the effort and aid the foundation of a School of Tropical Medicine at the Branch Hospital of the Seamen's Hospital Society, Albert Docks, London, E. The formation of a school for the study of tropical diseases was a peculiarly appropriate step for the Board of Management of this Hospital to take, for the patients in their wards were largely composed of sailors suffering from tropical ailments. Here was the material for study, and it only needed someone to initiate the idea, and to organise and finance the scheme to bring it to a practical issue.

The Colonial Office, under the stimulating lead of the Right Hon. Joseph Chamberlain, M.P. (at that time the Secretary of State for the Colonies), lent willing assistance, and contributed a sum of £3,550 towards the scheme.

Since then many liberal contributors have furthered the requirements of the School, and several of the Crown Colonies have contributed towards its maintenance and development.

Some £40,000 have been spent upon the School, yet it is satisfactory to know that the School is free of debt, and likely to continue so. In all the work of organisation Mr. Michelli has played an active and a prominent part, and we rejoice to think that his devoted services have been rewarded in a manner which reflects honour upon himself, and has given pleasure and satisfaction to all the members of the Board of the Seamen's Hospital Society, and to the staff of teachers at the London School of Tropical Medicine. We believe Mr. Michelli is the first secretary to a public hospital on whom an honour of the kind has been bestowed, and we take it that amongst the many able men who serve their hospitals in a like capacity, the decoration of Mr. Michelli will be regarded as a welcome recognition of how their efforts are regarded, not only by the King, but by the country generally.

Review.

ILLUSTRATED KEY TO THE CESTODE PARASITES OF MAN. By C. H. Wardell Stiles. Washington, 1906, pp. 104.

THIS small volume (Bulletin No. 25), issued by the Hygienic Laboratory of the Treasury Department, U.S.A., is an elaborate and carefully executed companion to the "Illustrated Key to the Trematode Parasites of Man" (Bulletin No. 17), issued by the same laboratory. Both these volumes deserve a better setting than has been given them. In their present form, however, they are eminently useful; the illustrations, mostly in diagramatic form, are excellent for teaching purposes, and the text will be found to be practical and easily followed.

Correspondence.

INTERNATIONAL CONGRESS FOR HYGIENE AND DEMOGRAPHY.

To the Editors of the JOURNAL OF TROPICAL MEDICINE.

DEAR SIRS,—I shall be very much obliged to you if you would have the kindness to publish the following notice in your Journal.

Yours faithfully,

Berlin, *November 14th*, 1906.

DR. NEITNER, *Secretary-General.*

THE FOURTEENTH INTERNATIONAL CONGRESS FOR HYGIENE AND DEMOGRAPHY.

Her Majesty the Empress of Germany has most graciously accorded her high protectorship to the work of the Fourteenth International Congress for Hygiene and Demography, which will take place in Berlin in September of next year.

TYPHUS AND SPOTTED FEVER.

To the Editors of the JOURNAL OF TROPICAL MEDICINE.

SIRS,—I see on p. 271 of your issue of September 1st, that the Mexican Government have offered three prizes of £4,000 each for discoveries connected with typhus, and that Dr. Terres, of Mexico, states that typhus is seldom met with below an altitude of about 2,000 feet. Is not this disease more probably the "Spotted Fever" of the Rocky Mountains? This fever has been known, since 1872, in some of the four neighbouring States of Nevada, Montana, Idaho, and Wyoming. It is often confused with typhus, because of the eruption which usually appears first on the wrists, ankles, and back, about the third day, and spreads rapidly over the rest of the body, lasting from eight to twenty-one days, or even longer; the spots are petechial, and sometimes coalesce, giving a mottled appearance to the skin. Among other symptoms resembling typhus there are injected conjunctivæ, photophobia, epistaxis, offensive breath, sordes on teeth, dry, brown tongue, and weak pulse. Hypostatic pneumonia is the most common complication; convalescence is slow, and there are many other minor resemblances to typhus. The American doctors who have studied the disease, and have taught us the little we know on the subject, are not usually very well acquainted with typhus, but they consider that the two diseases are distinct. Among symptoms which do not resemble typhus we hear of desquamation, jaundice, tenderness of the right iliac fossa, tympanitis, swollen joints, vomiting, enlarged liver and spleen. Mr. C. W. Stiles made a zoological investigation into the etiology of "Spotted Fever," in 1904, for the United States Government, and was unable to confirm the theories that the blood contained a piroplasma, or that it could be communicated by ticks to rabbits or other animals. His communication was published last year by the Hygienic Laboratory at Washington.

Yours truly,

Cavendish Square, London. F. M. SANDWITH, M.D.

Drugs and Remedies.

THE "TABLOID" BRAND.—We congratulate Messrs. Burroughs Wellcome and Co. on their successful defence of what would appear to have been an infringement of their rights to the exclusive use of

their designation for compressed drugs. A trading company wished to register the word "Tablones," to designate their products. This was refused by the Board of Trade and subsequently on appeal to the High Court of Justice. The several attempts to dethrone the magic word "Tabloid" has hitherto ended in deserved failure. There can be no doubt that words resembling "Tabloid," used by companies other than Burroughs Wellcome and Co., are only employed for one purpose. Surely we have enough originality left amongst us to devise catching names for new preparations, without seeking to come in conflict with existing terms.

The three following preparations are issued by Messrs. Martindale, 10, New Cavendish Street, London, W.:—

TYLMARIN, a new coumaric derivative. It has been commended for the treatment of tubercular glands, in conjunction with injection of the 22 per cent. solution of sodium-orthocoumarate and the glycerine solution of sodium cinnamate. The same drug is suggested as a treatment in malignant ailments.

SYRUPUS IODO-TANNICUS, is a palatable preparation containing iodide in loose chemical combination, and employed in the treatment of enlarged cervical glands.

SEDEFF contains suitable doses of opium, bismuth, and digestive ferments; it is useful in digestive derangements, especially those accompanied by vomiting, and in the sickness of pregnancy.

Books and Papers Received.

PROFESSOR GALLIO-VALERIO'S new work on the Mosquito is published by Edwin Frankfurth, 12, Grand Chene, Lausanne, Switzerland. The book is illustrated. Price 4.50 francs.

Notes and News.

LEPER COLONY IN THE PHILIPPINES.—A permanent leper colony has been established at Colion Island, in the Philippines. Some 200 lepers are now installed there. Four Roman Catholic Sisters have volunteered to nurse the lepers in the colony.

THE King of the Belgians has offered a prize of about £7,000 to any person, of any nationality, who shall discover a cure for sleeping sickness. A sum of about £10,000 is also offered by His Majesty for the purpose of making researches and experiments towards exterminating sleeping sickness.

R. KOCH is at present in Sese, Bugala, in Africa. The investigation of sleeping sickness is usurping the whole of his time.

ISTHMIAN CANAL COMMISSION.—From January 1st to August 31st, 1906, only one case of yellow fever was reported from the Canal Zone. During August, 1906, the mortality from the most prevalent diseases was as follows: Pneumonia, 94 deaths; malaria, 78; typhoid fever, 12; dysentery, 20; beri-beri, 5. The population of the part of the Isthmus from which these figures are obtained, numbers 75,000 people.

During September, 1906, pneumonia caused 86 deaths, and malaria 70. During the months of August and September, 1906, there were no fatal illnesses amongst the 4,800 Americans (whites) in the Canal Zone.

ACCORDING to our last news from India, the students of the Campbell (vernacular) Medical School of Calcutta had been out "on strike" for a week. According to the version of the affair as reported in the *Pioneer*, the cause of dissatisfaction in this particular case appears to be of a frivolous and personal character; but as the vernacular medical students have always shown themselves in the past as a very well-behaved set of young men, it may be taken that these recurring evidences of friction and discontent in these widely distant schools, are merely symptoms of a general feeling of dissatisfaction with the conditions prevailing in the service. It is to be hoped that the probably ill-advised turbulence of these boys will not prejudice Government against granting reasonable concessions in the matter of pay and prospects to this large and important service.

THE Punjab Government has before it a "Tenancy Bill," which includes some proposed enactments of medical interest. Clause 28 gives power to levy a tax to defray expenses connected with the sanitation and general administration of village sites. This should prove a very useful power, as apart from the theoretical position of the Government as the ultimate possessor of the soil, it deals directly as landlord to tenant in the case of the very extensive population of farm colonists, now settled on, till recently, waste lands, that have been reclaimed by irrigation.

Naturally enough, these chance collections of cultivators lack the power of cohesion and initiative of older villages, and the Government is in a far better position to make them models not only of cultivation, but of sanitation.

These newly irrigated lands are, as might be expected, extremely malarious, and for other reasons require special measures of sanitation.

An old village site can always be easily recognised by its elevation above the endless surrounding plains.

The Indian peasant is a bad hand at repairs, and often lets his mud-built homestead fall down when a little timely personal exertion might have kept it habitable for years to come.

The sun-dried bricks, of which the huts are built, are fabulously cheap, and cannot generally be so conveniently made on the site as on the banks of the nearest tank, so he does not clear away the site or utilise the old material, but roughly levels the heap and builds on the ruins, with the result, that in the course of the hundreds, and perhaps occasionally thousands of years, a site has been occupied, the

centre of it stands perhaps 50 or 60 feet above the general level of the ground. This elevation of the site is, of course, a valuable sanitary asset, but has the undesirable corollary of the environs of the site being honeycombed with irregular excavations holding dirty water throughout the greater part of the year. In the case of really old sites, the entire inhabited site is more or less surrounded and intersected with a miniature "lake district," the intricacies of which would puzzle an expert marine surveyor. The water they contain is for the most part indescribably foul, and one of the most urgent and insoluble of the problems of Indian sanitation is that of the betterment of the state of things that has resulted from the method of development of village sites above described.

Now the irrigation colonies just mentioned have only been started during the last few years, and it is most important that the Government, in its strong position as direct landlord, should step in and regulate the development of these new villages before the evils that have been touched upon have crystallised into established facts.

It is extremely desirable that the inhabited site hould be raised well above the general level of the rrigated fields, and it is also most important that the subsoil beneath it should be drained. Now both these objects can be attained by making deep and properly graded cuttings to the nearest practicable outfall, and utilising the spoil to raise the site, but such operations can only be undertaken by the Government itself, and the power to levy a small tax to cover the interest of the capital outlay will be a valuable one, which we trust Government will promptly utilise, and justify by works of sufficient magnitude to demonstrate that irrigation is not necessarily incompatible with a good standard of public health.

THERE is a want of uniformity in the attitude of the various provincial governments in India in the matter of dealing with the growing evil of the cocaine habit. No steps, for example, have been taken in the United Provinces of Agra and Oudh, to bring cocaine under the provisions of the Excise Acts, and the result is, it appears, that these provinces form centres from which smuggling can easily be conducted into neighbouring provinces where the authorities have acted more wisely in the matter.

THE current (November) number of the *Indian Medical Gazette* includes two useful "Notes" by members of the Calcutta Plague Staff.

In the first Captain V. B. Nesfield, I.M.S., strongly advocates the use of chlorinated lime as a disinfectant. He points out that owing to lack of penetrative and diffusive power, the metallic germicides, such as mercuric perchloride, cupric sulphate, &c., though extremely powerful when they can be brought into actual contact with bacteria, fail in practice on account of the impossibility of securing contact. A drop of a cultivation, for example, of *B. coli*, placed on a scrap of paper, and floated on some such disinfectant, remains quite unaffected for a long time. The chlorine gas, however, given off by chlorinated lime diffuses itself into chinks and crannies, and even permeates porous materials. The main objection to the agent is the difficulty of keeping it in good condition in a hot climate, and he therefore recommends that it should be sealed in glass tubes containing $2\frac{1}{2}$ oz. each, at a cost of $2\frac{1}{2}$d. each. Each of these tubes suffices to make eighty gallons of a germicide lotion.

Chlorine is, of course, an excellent insecticide, but we doubt if it would be given off in sufficient quantity from such a lotion in a sufficiently concentrated form, to secure the destruction of flies; as if it were so, its application would obviously be dangerous to the disinfecting gangs; and failing the power to destroy insects no germicide can be considered reliable in dealing with plague.

Chlorine can, however, be easily and cheaply manufactured, with a suitable apparatus, by pouring slightly diluted sulphuric acid on a mixture of common salt and binoxide of manganese, the whole of the chlorine contained in the salt being liberated.

There would be no difficulty whatever in contriving a suitable apparatus to contain a charge of the salt and dioxide, into which an appropriate charge of acid might be tipped by pressing a button. All openings but one having been closed in the room to be disinfected, all that would be necessary would be to place the apparatus within the room, press the button, and immediately leave the room, closing the door behind one, as if provided with a fairly long flexible tube, the gas would not begin to issue from it until ample time had been given to effect the small manipulation necessary.

The second note, from the pen of Dr. W. C. Hossack, deals with the species of rats found in Calcutta. He finds that the rats concerned are *Nesokia bengalensis*, or Indian mole rat, 60 per cent.; *Mus decumanus*, the short-tailed grey rat, 26 per cent.; *M. alexandrinus*, a local race of *M. rattus*, the European long-tailed "black rat," 14 per cent.; and *N. nemonvagus*, the lesser Bandicoot, which is rare.

If we remember rightly, Captain Glen Liston found the black rat relatively much commoner in Bombay, and, as he points out, that, owing to its habits, it is much more commonly concerned in carrying plague than the other species, its rarity in Calcutta may serve to explain the comparatively lightness of the incidence of plague in Calcutta from plague.

FEVER is becoming seriously prevalent in the frontier cantonments. A Peshawar correspondent writes: "The great topic of conversation at present is the tremendous prevalence of fever, and it seems likely that owing to it, the divisional manœuvres, which were timed to take place about November 27th, will have to be abandoned, some 20 or 40 per cent. of the garrison being affected. The type seems to have reverted to the Peshawar fever of some fifteen years ago, which, happily, has been dormant for some years, and greatly resembles cholera."

A Rawal Pindi correspondent writes: "Pindi is still suffering under a veritable wave of fever of a most virulent type, and labour of any sort is scarcely procurable. Large fields of crops in the vicinity of the town stand uncut, long since over-ripe, bearing silent

witness to the melancholy fact of the prevailing sickness."—*Pioneer Mail.*

It may be taken for granted that no adequate anti-malarial measures have been attempted in either of these stations. WHY NOT?

Personal Notes.

INDIAN MEDICAL SERVICES.

Arrivals reported in London.—Lieutenant-Colonel J. Smyth, Lieutenant W. F. Brayne, Lieutenant C. H. Barber.

Extensions of Leave.—Major W. Pilgrim, furlough to February 3, 1907; Lieutenant-Colonel R. H. Castor, one week furlough; Major J. T. Calvert, study leave, January 15th to July 14th, 1906; Captain D. N. Anderson, 6 m. medical certificate.

Permitted to return to Duty.—Captain A. Murphy.

Postings.

Major H. E. Drake Brockman, Residency Surgeon, Western Rajput States.

Lieutenant-Colonel P. D. Pank, Residency Surgeon, Jaipur.

Lieutenant-Colonel W. H. B. Robinson, Agency Surgeon, Bikanir.

Major A. L. Duke, Residency Surgeon, Bangalore.

Major T. W. Irvine, Senior Surgeon and Sanitary Commissioner, Mysore.

Lieutenant J. F. Boyd, to Civil Medical Duties, Kohat.

Lieutenant B. E. M. Newland, to Civil Medical Duties, Chitral.

Lieutenant-Colonel A. W. Dawson, to Civil Medical Duties, Roorkee.

Civil Assistant-Surgeon Purna Chandra Mukerji, to Civil Medical charge, Gonda district.

Lieutenant-Colonel S. H. Henderson, to be Superintendent, Central Jail, Agra.

Colonel H. Hendley resumes charge as Civil Surgeon, Lahore, and Professor Midwifery and Forensic Medicine.

Major E. V. Hugo, to Civil Surgeon, Lyallpur.

Major G. F. W. Ewens, resumes charge as Superintendent Punjab Lunatic Asylum.

Major P. J. Lumsden, to be Agency Surgeon, Bhopawar.

Major N. Burden, to be Agency Surgeon, Gilgit.

Captain McCarrisa, to be Agency Surgeon, Alwar.

Major Scott Montcrief, to be Agency Surgeon, Mewar.

Major J. Fisher, to be Agency Surgeon, Eastern Rajput States.

Lieutenant-Colonel A. M. Crofts, C.I.E., to be Administrative Medical Officer, N.W. Frontier Province.

Lieutenant-Colonel G. W. P. Dennys, to be Civil Surgeon, Peshawar.

Captain Fleming, to Consulate Medical Officer, Turbat-i-Haidari.

Captain L. J. M. Deas, to be Residency Surgeon, Gwalior.

Captain Macmillan, services at disposal Government Eastern Bengal.

Captain Munro, services at disposal Government Bengal.

The under-mentioned officers are permitted to continue in their appointments of specialists in prevention of disease: Major Julian, Peshawar; Major Taylor, Kamptee; Major Anderson, Meerut; Captain Spiller, Allahabad; Captain Smallman, Secunderabad; Captain Brunskill, Rangoon; Lieutenant Watson, Karachi.

The services of the following officers are placed at the disposal of the Government of India in the Home Department, with effect from October 16th, 1905:—

Lieutenant-Colonel R. N. Campbell, M.B.; Major D. R. Green, M.B., and Captains W. D. Hayward, S. Anderson, T. H. Delany, H. Inness, M.B., W. V. Coppinger, A. C. Gilchrist, and T. H. Watling.

Leave.

Major E. Jennings, 2 y. combined leave.

Captain H. Ainsworth, 7 m. combined leave.

R.A.M.C.

Lieutenant-Colonel T. B. Winter, to charge of Station Hospital, Bareilly; Captain W. Davis, to inspection of routes, in connection with Agra concentration; Major Mould, to Agra for duty; Captain J. F. Martin, from Northern Command to Poona Division; Lieutenant-Colonel G. Scott is granted six months' leave out of India.

COLONIAL MEDICAL SERVICE.

A. L. Hoops, M.D., D.Ph., State Surgeon and Superintendent of Prisons, Kedah, Malay Peninsula, has been appointed to act as Adviser to the State of Kedah during the absence on leave in Europe of Mr. G. C. Hart.

PECULIAR ERUPTIONS OF THE SKIN IN INDIA, DUE TO VEGETABLE AND INSECT LIFE, AND THEIR TREATMENT.

By Major G. H. FINK, I.M.S., M.R.C.S., L.S.A.Lond.

MOST people who have lived in India will have seen from time to time curious forms of skin eruption due to certain vegetable and insect life. These are peculiar to certain provinces and districts in India. Bengal and Assam produce some which are not to be seen in any other part of the country, and these very often are powerful in their action and produce vesication of the skin, burn, and create discomfort which resembles that of a strong blister or a hot iron applied to the skin.

In parts of Assam, such as the North Lushai Hills, one well-known leaf which is cordate in shape, bluish-green in colour, of the size of the hand, which grows in the jungles, possesses this powerful property of a vesicant if touched.

But the effects of a certain spider lick or bite is to be seen frequently in children in Bengal, when the face is generally the part affected, owing to this part of the body coming frequently into contact with spider webs. The result is often an eruption on the lips or chin, resembling *Herpes*, which, if untreated, goes on to resemble *Impetigo contagiosa*, if you compare these eruptions with it.

Treatment. — The most effectual treatment of a spider's lick or bite is as follows:—

Take a basin of cold water and let the patient hold his or her head over it. Now get a few lumps of mustard oil cake (which is to be had in almost every oilman's shop, since the cake is obtained after expressed mustard oil is manufactured, and is used largely to fatten cattle), burn these in a charcoal fire till of a black colour. Drop the burning lumps into the basin of water, and allow the smoke and fumes which rise to come into contact with the part of the patient's skin which is affected, twice a day, for two or three days. The result is a perfect cure.

On examining the surface of the basin full of water, there will be seen a large number of transparent little droplets of a yellowish-white colour, and about the size of a pin's head, which look like so many eggs of lepidopterous insects, or like the simple follicles of the secreting organs of the spider tribe (*Arachnida.*)

The study of Spiders, Scorpions and the Acarida, as well as the parasitic Acarida (to which *Demodex folliculorum* belongs) is very necessary, and it would be therefore essential to devote attention to such

insect and parasitic life, as well as the Lepidoptera, which create skin eruptions of a vesicular and follicular type, and to their proper treatment in the early stages, otherwise the character of the affection is masked by the lapse of time, and its origin very often lost.

MOSQUITO BRIEF PREPARED BY THE AMERICAN MOSQUITO EXTERMINATION SOCIETY.

(1) THERE are over 100 species of mosquitoes in the United States.

(2) Mosquitoes breed only in water. They may breed in any kind of quiet water unstocked with destroying fish.

(3) Mosquitoes generally require from one to three weeks to develop from eggs to winged insects in warm weather, longer in cold weather. Some female mosquitoes three days old lay eggs, the average is greater. Some species lay as many as three or four hundred eggs at once, some lay them singly. Mosquitoes may live several months (as shown by hibernation and otherwise), but probably few live over a month.

(4) Mosquitoes do not breed in grass, but rank growths of weeds or grass may conceal small breeding puddles, and form a favourite harbouring place for adults. The pitcher plant holds sufficient water to breed a rare and small species.

(5) Different species of mosquitoes have as well-defined habits as different kinds of birds, flies, &c. Some are domestic, some wild, some migratory.

(6) Most domestic mosquitoes breed in fresh water, fly short distances, and habitually enter houses.

(7) Most migratory mosquitoes breed in salt and brackish marsh areas, and can fly long distances. They are not conveyers of malaria.

(8) Rigid tests, both direct and eliminative, have proved that certain species of mosquitoes are the only known natural means of transmitting malaria and yellow fever. Some other diseases are known to be conveyed by mosquitoes.

(9) Of the domestic varieties, the dangerous malarial mosquitoes (several species of the genus *Anopheles*) are among the most generally distributed. They seem never to travel far, only a few hundred yards.

(10) A most common and dangerous domestic mosquito in the south and the Tropics is *Stegomyia fasciata*, which is the natural conveyer of yellow fever.

(11) Mosquitoes are known to bite more than once, as can be seen by observation, and is proved by the transmission of disease from an infected person to a new subject.

(12) Mosquitoes are a needless and dangerous pest. Their propagation can be largely prevented by such methods as drainage or filling of wet areas, removal, emptying or screening of water receptacles, spraying standing water with oil where other remedies are impracticable. Attention should be paid to cisterns, house-vases, cesspools, road basins, sewers, watering troughs, roof gutters, old tin cans, holes in trees, marshes, swamps and puddles. As malarial mosquitoes may be breed in clear springs, the edges of such places should be kept clean, and they should be stocked with small fish. The breeding and protection of insectivorous birds, such as swallows and martins, should be encouraged. Thorough screening of houses and cisterns is necessary to prevent the spread of malaria or yellow fever. The continued breeding of any kind of mosquitoes, with the attendant menace to public health and to the life and comfort of man and beast, is therefore the result of ignorance or neglect.

UNIVERSITY OF EDINBURGH.

CERTIFICATES IN TROPICAL MEDICINE.

IN the Calendar of the University of Edinburgh the following candidates are announced to have gained certificates in the department of Diseases of Tropical Climates, conducted by Dr. Andrew Davidson.

First-class Honours.

Alexander Edington, M.D.	Equal (Medallists).
Major Owen St. John Moses, I.M.S.	
D. Morley Mathieson, M.A., M.B.	
James Sutherland Edwards.	
Major Bryson, I.M.S.	
William H. Hill, M.D.	
Charles Chaves, M.B.	Equal.
W. M. P. Henderson	
K. R. Tampi.	
J. S. Manson.	
Robert M. Wishart.	
P. Lornie.	
J. A. MacLeod	Equal.
Arthur Dangerfield, M.B.	
Halliday Gibson Sutherland	
W. O. Sclater.	
E. W. Dyer.	
John Hunter, M.B.	
A. M. Dick.	
A. J. S. Walwyn.	
Graham Robertson	Equal.
John Macdonald	
Harley P. Milligan.	

Second-class Honours.

J. Theodore Young, M.B.	Equal.
Hugh Jamieson, M.D.	
T. H. Dickson	

PRELIMINARY LIST OF SUPPORTERS OF THE COLLECTION IN AID OF THE GREEK ANTI-MALARIA SOCIETY.

UNDER THE PATRONAGE OF H.R.H. PRINCESS CHRISTIAN.

HIS EXCELLENCY SIR FRANCIS ELLIOT, G.C.V.O., K.C.M.G., British Minister at Athens.

His Excellency M. Metaxas, G.C.V.O., Greek Minister in London.

Mr. Sp. Acratopulo, Liverpool.

Dr. Clifford Allbutt, F.R.S., Professor of Medicine, University of Cambridge.
Alderman J. Ball, Lord Mayor of Liverpool.
Mr. E. Benachi, President of the Greek Community of Alexandria (Egypt.)
Mr. R. C. Bosanquet, Professor of Classical Archæology, University of Liverpool, and Institute of Archælogy.
Sir James Creighton Browne, F.R.S., Treasurer, Royal Institution of Great Britain.
Mr. James Cantlie, Editor JOURNAL OF TROPICAL MEDICINE.
Professor Carter, M.D., Chairman, Professional, Committee Liverpool School of Tropical Medicine.
Dr. Caton, Emeritus Professor, University of Liverpool.
Mr. T. E. Collcutt, F.R.I.B.A., President of the Royal Institute of British Architects.
Mr. M. Corgialeno, President of the Greek Community in London.
Vice-Chancellor A. W. W. Dale, University of Liverpool.
Professor the Rev. S. R. Driver, Regius Professor of Hebrew, Oxford.
Sir John Evans, F.R.S., President, Royal Numismatic Society.
Dr. Frazer, LL.D., Trinity College, Cambridge.
Mr. J. Garstang, Institute of Archæology.
Mr. Griffiths, United States Consul, Liverpool.
Professor Herdman, F.R.S., President of the Linnean Society of London.
Sir Alfred Jones, K.C.M.G., Chairman, Liverpool School of Tropical Medicine, and President, Liverpool Chamber of Commerce.
Professor Macalister, M.D., St. John's College, Cambridge.
Dr. Mahaffy, D.D., Trinity College, Dublin.
Mr. B. A. Malandrinos, Greek Consul in Liverpool.
The Right Hon. Viscount Mountmorres.
Sir Shirley Murphy, Medical Officer of Health, London.
Mr. A. Natzio, Manchester.
Mr. G. Hall Neale, President, Liverpool Academy of Arts.
Mr. P. E. Newberry, Institute of Archæology.
Sir Christopher Nixon, LL.D., Ex-President, Royal College of Physicians, Ireland.
Dr. G. H. F. Nuttall, Ph.D., Professor of Protozoology, Cambridge.
Dr. Osler, F.R.S., Professor of Medicine, University of Oxford.
Mr. Alex. Pallis.
Mr. Rushton Parker, F.R.C.S., Professor of Surgery, University of Liverpool.
Sir Richard Douglas Powell, Bart., M.D., President, Royal College of Physicians.
Mr. G. C. Ralli, Liverpool.
Messrs. Ralli Brothers, London, Liverpool, Manchester, &c.
The Right Hon. Lord Rayleigh, O.M., President of the Royal Society.
The Right. Hon. Lord Reay, G.C.S.I., LL.D., President of the British Academy.
His Excellency Sir John Rodger, K.C.M.G., Governor of the Gold Coast.
Dr. J. Rutherford, Harrogate.
Mr. Watson Rutherford, M.P., Liverpool.
Dr. C. G. Savas, Professor of the University, Athens.
A. E. Shipley, Esq., F.R.S., Cambridge.
Mr. J. J. Stavridi, Greek Consul-General in London.
The Right. Hon. Lord Stanley, K.C.V O., C.B.
Mr. D. Steele, Lake Kopais Company, Greece.
Dr. Traill, LL.D., Provost of Trinity College, Dublin.
Sir Frederick Treves, Bart., F.R.C.S.
Robert Wallace, Esq., F.R.S.E., Professor of Agriculture, Edinburgh University.
Sir Henry Wood, Secretary, Society of Arts, London.
Mr. G. Zlatano, Manchester.
Mr. G. B. Zochonis, Manchester.

Geographical Distribution of Disease.

As information arrives we publish, under this heading, the principal diseases met with in tropical and sub-tropical countries, so that those interested in the Geographical Distribution of disease may have a means of gathering information concerning the prevalent ailments in different parts of the world.

PREVALENCE OF CANCER.

To the Editors of the JOURNAL OF TROPICAL MEDICINE.

SIRS,—In reply to your correspondent, Dr. Branch, I would mention that I can recall, during a practice here of eleven and a half years, four cases of epithelioma in Soudanese slave women brought to Morocco, and without any admixture of Arab blood. They came under notice at a late stage, and died with disseminated growths. I may have had more in the dispensary, but my case books do not mention the colour or race of the patients.

I think cancer of all kinds, except rodent ulcer, which I have never seen here, is at least quite as common as in England. Of course, the Arabs largely predominate over the pure blacks. My work, being confined to women and children, excludes case of cancer special to men.

Yours faithfully,

Women's Hospital, Tangier, Morocco. GABRIELLE BREEZE, M.B.

India.

Malignant Diseases.—At the London Mission Hospital Tammaladugu, Southern India, the following operations for malignant diseases were performed during 1905:—

Epithelioma—arm (excised)	... ...	1
loin ,,	... ...	1
anus ,,	... ...	1
penis, partial removal	...	1
total extirpation	..	1
tongue, removal of half		1
cheek and lip	... ...	3
lower jaw, half removed		4
palate	... ...	1
scirrhus of breast amputation	... ...	8
Sarcoma breast, amputation	... ...	1
Rodent ulcer	... ...	1
Myosarcoma buttock	... ...	1
Lymphadenoma	... ...	1
Cancerous degeneration of ovarian tumour	... ...	1

Recent and Current Literature.

A tabulated list of recent publications and articles bearing on tropical diseases is given below. To readers interested in any branch of tropical literature mentioned in these lists the Editors of the JOURNAL OF TROPICAL MEDICINE *will be pleased, when possible, to send, on application, the medical journals in which the articles appear.*

"The China Medical Missionary Journal," September, 1906.

I. AN UNDESCRIBED FORM OF ASCARIS AND ITS EGG.

Logan, O. T., writing from China (place not stated) states that he has found an undescribed egg in the fæces. The egg may be, he suggests, an abortive or partially developed egg of a lumbricoid. He has further noticed that the parent female worm has a constriction about one-sixth inch wide, which encircles the body at the junction of the middle and anterior thirds. These observations correspond to those made by Dr. Crichton Wellman in South Africa, who found a worm with a constriction similar to that described by Dr. Logan, who asks if this is a new species.

An interesting clinical fact noted by Dr. Logan is that he had seen a round worm passed by the urethra.

II. From Hangchow, Fokien, a communication concerning the prevalence of diseases was as follows: (1) Beri-beri: rare, a few cases in twenty-five years, not endemic. (2) Cholera: sporadic cases only. (3) Dysentery: common, mostly chronic, mortality not high. (4) Hernia: very common. (5) Malarial fever: common and virulent. (6) Plague: no plague. (7) Pneumonia: common and deadly. (8) Typhoid: common, but of mild type. (9) Urinary calculi: several cases every year operated on.

Of the diseases enumerated in this table, the most unexpected is the frequency of hernia. Most observers in China hitherto have constantly remarked upon the extraordinary few cases of hernia seen amongst the Chinese.

III. SUICIDES BY OPIUM IN CHINA.

In the annual report of the Chinese Hospital, Shantung Road, Shanghai, for the year 1905, the number of attempted suicides by opium is remarked upon. No fewer than 318 cases of this nature were brought to the Hospital, 196 being males and 122 females. Of this number, 25 died and 293 recovered. When one thinks of the number of cases never brought to hospital, and that the above figures represent the cases brought to one hospital only, the extent of attempts upon life by this means throughout the length and breadth of China must be appalling.

IV. MALIGNANT DISEASES IN CHINA.

Dr. Kuhne, in his report of the Tungkun Hospital, states: "Cancer and epitheliomata are not so frequent as in Europe; on the other hand, fibromata have a tendency to become malignant, and lymphadenomata are often a cause of death."

"Journal of Amer. Med. Soc.," April 28, 1906.

I. A REVIEW OF CANCER IN THE UNITED STATES OF AMERICA, ACCORDING TO THE TWELFTH (THE LAST) CENSUS. By Guthrie McConnell, M.D.

Conclusions.

(1) That cancer appears to have actually increased in the United States; 12·1 deaths per 100,000 population in the past ten years.

(2) That the death-rate is higher in the rural districts and small towns than in the cities.

(3) That native whites suffer much less than the foreign whites.

(4) That the death-rate amongst the foreign whites in the United States is only apparently greater than in their own homes.

(5) That 63·1 per cent. of all cancer cases are in women, and 36·9 per cent. in men.

(6) That those employed in hard outdoor work have a higher cancer mortality than the sedentary classes.

(7) That the areas showing the greatest mortality are mountainous regions that are well watered and timbered.

(8) That cancer does not seem to be generally more prevalent along rivers.

(9) That those cities in which there are both a large German population and large brewing interests do not show a corresponding increase in cancer mortality.

(10) That cancer mortality is greatest in persons of 65 years and over.

(11) That the average age at death is 58·1 years.

II. MALARIA INFECTION IN CERTAIN NATIVE VILLAGES OF THE CANAL ZONE. By A. I. Kendall, M.D.

Summary and Conclusions.

(1) Malaria existed in certain towns of the Canal Zone at the time this work was done to such an extent that over 50 per cent. of the native born and 70 per cent. of the foreign born harboured parasites in their peripheral circulation.

(2) This high percentage of infection does not necessarily mean that a corresponding number present febrile symptoms; in fact, many do not.

(3) This high percentage of infection is a menace to the health of those who, by reason of their work, may be compelled to remain in such towns, particularly because of the wide distribution of the *Anopheles albipes*, a mosquito shown to be capable of transmitting malaria. Other Anopheles to a lesser extent may also be factors in distributing malaria.

(4) The æstivo-autumnal malaria is the prevalent type; the Chagres fever is, in all probability, a severe æstivo-autumnal infection. Pernicious malaria is not caused by a new parasite, but by an æstivo-autumnal organism of exalted virulence.

(5) Natives and their descendants or, in general, the descendants of those who have lived continuously on the Isthmus of Panama for many years, at birth have, to a certain degree, an inherited immunity; an active immunity, which is by no means absolute, is generally acquired, becoming manifest at about the age of 16. The foreign born acquires a tolerance to the malarial organism; this tolerance, however, is not as great, nor does it begin as early, as is the case with natives.

(6) Malaria is an environmental disease; occupation has very little to do with the cause of this disease.

(7) Quinine in moderate daily doses, while not absolutely guaranteeing freedom from malaria, or completely driving organisms from the circulation, has an important preventive and curative effect.

"C. R. Soc. Biol.," T. lx., p. 659.

SERUM REACTION DURING THE COURSE OF MEDITERRANEAN FEVER.

Soulie, H., and Garden, V. In thirteen cases in which the agglutinating power of the serum was tested daily, the authors found this variable; and in the same patient the power might disappear altogether on certain days. The serum reaction of 122 patients, suffering from different diseases, for the *M. melitensis*, was always negative up to $\frac{1}{30}$.

The agglutinin is destroyed by heating for five minutes to 60°, a quite exceptional fact, which is duly emphasised.

A CASE OF INVASION OF THE OVARY OF A CRAB BY THELOHANIA MÆNADIS.

Pérez, Ch. (*ibid.*, p. 1091), describes an exceptional case in which the ovary of the crustacean was infected by this microsporid in the stage of young sporonts. The parasite had completely invaded the ovary, forming the greater part of the mass. There were a few healthy ovules, some foci of germinal proliferation, eosinophile amœbocytes, and reticules of follicular phagocytes, evidently engaged in absorbing large vitilline patches, which were evidently the remains of large ovules.

THE BACILLI OF A DYSENTERIFORM EPIDEMIC AT TUNIS.

Nicolle, C., and Cathoire (*ibid.*) isolated two forms: (1) A bacillus of a strain resembling that of Shiga and Chantemesse, and differing from that of Flexner II., which ferments maltose, dextrine, saccharose, and soluble starch only, and produces only indol in peptonised water. The ingestion of a few drops of the culture was sufficient to produce the disease in a young rabbit. (2) A mobile bacillus, the cultures of which smelt like those of *B. coli.* Subcutaneous innoculation of an adult rabbit with 1 cc. of this culture in bouillon failed to reproduce the malady. It produced indol in peptonised water, but did not ferment lactose. It did not agglutinate with dysenteric serum, and the corresponding serum did not agglutinate the micro-organism of true dysentery.

THE EXPERIMENTAL STUDY OF BERI-BERI.

Salanone, Henri (*ibid.*, p. 1117). The research in question was made in the bacteriological laboratory of Hanoi, and consisted in inoculating the dura mater or substance of the pectoral muscle of pigeons with an emulsion of the pneumogastric nerve of a beri-beri case. There resulted a progressive paralysis of the legs and wings.

The blood and pulp of the internal viscera of the same patient proved to be harmless when employed in the same way.

From these pigeons M. Salanone has isolated a diplococcus having many of the characters of that described by Okata and Kokubo. It will not stain by Gram's method, slightly clots milk, and attacks lactose.

The cultures on bouillon and on serum have a smell like stale fish. This microbe kills rabbits, mice, guinea-pigs, pigeons, fowls, and monkeys when inoculations are performed either *viâ* the dura mater, the peritoneum, or the trachea, and when the case terminates quickly, the lesions of acute beri-beri are very obvious.

Marked vaso-motor paralysis, with congestion of the internal organs, degeneration of the heart muscle, effusions into the peritoneum, pleura, and pericardium. A pure cultivation of the diplococcus was recovered from the heart-blood of the mouse. In fowls and monkeys this disease takes a chronic course, and in the monkey it recalls the "dry" form of beri-beri, with polynephritis, typical paralysis of the extensors of the limbs, marked wasting, and, to a certain extent, muscular atrophy.

"Philippine Journal of Science," T. i., p. 169.

BERI-BERI IN THE JAPANESE ARMY DURING THE LATE WAR.

Herzog Maximilien. In August, 1905, the author proceeded to Japan, to study beri-beri, of which some 80,000 cases had occurred in the Japanese Army, and to study a coccus, which was believed to be the cause of the disease by the Japanese physicians, Okata and Kokubo. The coccus was described by the latter in the *Journ. Milit. Surg. Assoc.*, September, 1905, as follows, and was named by them *Kakkecoccus*:—

"A diplococcus, scantily found in the blood of cases of beri-beri, immobile, without capsule, and staining well with analine colours. By pricking the region of the trapezius after cleansing the skin, they found this coccus in the blood in 65 cases, both by culture and by the examination of cover-slips; in 11 cases by the examination of the latter only, the cultures being negative; in 19 cases by culture, the microscopic examination being negative; while in 34 cases the examination was absolutely negative. The diplococcus grows rapidly on gelose at 37°, and very slowly at 10°. In bouillon, 37°, there was a greyish deposit at the bottom of, and adhering to the sides of the tubes, the liquid remaining quite clear; in gelatine no liquefication; in serum a fine grey cultivation; on potato a bright yellow deposit; does not ferment sugar; and does not clot milk. They isolated the same microbe from the urine 15 times, and from the stools in 45 cases."

The results of inoculating animals with the blood of beri-beri cases, with cultures of the coccus, or with the spleen of infected mice were indecisive: 3 rabbits out of 21, and 15 mice out of 64 succumbed, while 7 guinea-pigs all survived. Kokubo has prepared a serum by inoculating rabbits, which in a hanging drop agglutinated the coccus in a dilution of 1 per cent. in two hours.

Following Kokubo's methods, Herzog succeeded in isolating the coccus from the urine in 8 out of 40 cases, but he failed to isolate it from the blood of patients; and he points out that the precautions taken by Kokubo would not prevent the blood obtained from being contaminated by the secretions of the sudorific and sebaceous glands. They were not allowed to take blood directly from the median cephalic vein.

In the only autopsy that could be obtained the coccus was isolated from the kidneys and the meningeal fluid.

On returning to Manila, Herzog inoculated monkeys and other animals with the coccus, but, as yet, with indecisive results. He is, however, continuing his researches.

"Archiv. f. Schiff. und Tropen-Hyg.," T. x., p. 399.

PRELIMINARY NOTICE ON THE KAKKECOCCUS AS A CAUSE OF BERI-BERI.

Truzuki obtained a diplococcus 7 to 8 μ by 4 to 6 μ from the urine in 18 out of 65; and from the stools in 22 out of 30 cases of beri-beri. The organism exhibited only the Brunonian vibration, and was a facultative anærobe which produced no spores, and did not liquefy gelatine. It is stained by Gram's method, and grows on ordinary media at laboratory temperature, but best at 37°. Either in culture media or in the intestine it produces a toxin, which acts selectively on the nervous centres.

The author claims to have reproduced the characteristic symptoms of beri-beri in animals, but only by intra-cerebro-spinal inoculation, and states that his microbe agglutinates with the serum of patients affected with the disease. He further states that his diplococcus may be found in the intestine of healthy persons, but regards this as a parallel case to that of such persons acting as carriers of the cholera vibrio. It may be noted that this organism stains by Gram's method, whereas, as noted above, Herzog found that Kokubo's coccus did not do so. Altogether it seems doubtful if Truzuki is really dealing with the same organism, and it seems more than doubtful that his can be considered the true organism of beri-beri.

"Journ. Americ. Med. Assoc.," April 28, 1906.

GENERAL INFECTION BY A PROTOZOON PRODUCING A PSEUDO-TUBERCULOSIS OF THE VISCERA.

Darling, Dr. J. T. Writing from Acton, in Panama, the author describes a curious case of what appeared to be general miliary tuberculosis, but which on *post-mortem* examination proved to be due to an invasion of the organs by bodies which he regards as protozoa, for which he proposes the name *Histoplasma capsulata.* The supposed protozoa consisted of round or ovoid bodies about three microns long, provided with a sort of capsule, contents of which are variable as regards chromatin. They present some resemblance to the Leishman-Donovan bodies, and were sometimes combined into irregular masses like miliary tubercles. In the lungs these bodies occupied the interior of the alveolar epithelial cells, and in the liver the endothelial and hepatic cells. In the spleen and bone-marrow, on the other hand, the parasites were free in the plasma, though they were also found within the mononuclear leucocytes. He has since met with a second case of the disease.

"Philippine Journ. Sc.," 1906, p. 533.

TROPICAL SPLENOMEGALY.

Wooley, Paul G. The symptoms of seven cases observed by the author had much in common with Kala-Azar: Diarrhœa, enlargement of the spleen, transitory œdema an irregular temperature, rheumatoid pains, wasting and

feebleness, and probably anæmia. Hypertrophy of the liver is not a constant symptom, and quinine proved useless, the most important symptom being the hypertrophy of the spleen. In the Philippines, at any rate in Wooley's cases, the symptoms are not due to the *Piroplasma Donovani*, nor did they appear to be referable to the effects of malaria or syphilis; but he regards them as rather of intestinal origin, and due to ulcerations or other inflammatory lesions. In one of his cases, diagnosed as an instance of "Banti's" disease, Wooley isolated, both before and after death, a microbe in the form of a rodlet or diplococcus, staining well by Gram's method, and yielding a characteristic cultivation; but the injection of monkeys with the microbe gave only negative results. He concludes, therefore, that a variety of distinct morbid conditions are confused under the title of febrile tropical splenomegaly.

"C. R. Soc. Biol.," T., lx., p. 1149.

PROTOZOA OF ORIENTAL SORE.

Billet, A., found in a case originating at Ismailia, the protozoon described by Wright, Margenovski, and Bogroff, and gives a good description of the organism. With respect to the mechanism of propagation of the disease, he notes a case in which one of these sores developed exactly on the site of a mosquito bite. Now Ismailia, Touggourt, and Bokia are all places where the *Anopheles chaudoyei* has been found, and the distribution of this mosquito in Algeria corresponds exactly with that of "Biskra boil."

Billet, A. (*ibid.*, p. 1151), on a case of intermittent œdema associated with *Filaria loa*.

The author describes a case of the above such as would be described by us as Calabar swellings. An adult specimen of *Filaria loa* was extracted from the left lower eyelid. Some time after young filaria having all the characters of *F. diurna* were found in the blood, during the day only, associated with a marked eosinophilosis.

"Deutsche Med. Wochenschrift," August 16, 1906.

Meyer found in cases of dysentery the *Entamœba histologica* of Schaudinn.

"La Presse Medicale," April 28, 1906.

BANTI'S DISEASE.

Noumanbey maintains that the term Banti's disease should be confined to cases in which there is enlargement of the spleen of long standing, anæmia, enlargement of the liver, and ascites. He is of opinion that malaria is the cause of the disease. He found malaria parasites in one case. It may be remarked that although malaria parasites were found in one case, it is mere assumption to affirm that they stood in the position of cause and effect.

"Bulletin de l'Academie de Médicin," vol. lxx., No. 32.

PATHOGENESIS AND PROPHYLAXIS OF MALARIA.

Kelsch accepts the mosquito theory of the malaria infection, but considers that other modes of infection exist, citing turning up of the soil, exceptionally hot seasons, ingestion of dust-laden food, fatigue, and general unhygienic conditions. He asserts that the geographical distribution of Anopheles and malaria do not coincide. Kelsch has never known of a case of direct transmission of malaria from man to man.

"Medical Record," July 28, 1906.

Moulden W. R., from observation on prisoners in Manila, finds that copper has a selective action on dysentery due to *Amœba coli;* copper solutions are better borne than quinine; patients make a more rapid recovery under its use, gaining flesh and strength more rapidly than under any other method; and, most important of all, cases remain cured, provided, of course, that treatment is kept up a reasonable time after the disappearance of the amœba from the stools.

"Medizinische Blatter," March 8, 1906.

ANKYLOSTOMA AND MALARIA.

Schewald states that in Brazil many patients with malaria harbour ankylostomes. Anthelmintics, by getting rid of the worms, also cause the disappearance of the malarial symptoms without taking quinine.

The worms usually contain malarial parasites, which enter by the alimentary canal of the ankylostome and pass to the salivary glands, as in Anopheles; the parasite is not found in the ova, but malaria may possibly be transmitted or acquired through eggs.

When the ankylostome sucks blood, the malarial organisms are injected into the blood-current of the host. This may explain refractory cases of malaria, and the recurrence of attacks at the same time each year.

"British Medical Journal," October 20, 1906.

SPIROCHÆTES IN YAWS AND GRANULOMA PUDENDI.

MacHennan reports that he has discovered spirochætes in smears from a papilloma occurring in recurrent yaws. The spirochæte met with resembled the *Spirochæte pallida*, but the staining (by Giemsa's solution and gentian violet) proved fainter. In the granuloma tissue itself a few organisms resembling *Spirochæte refringens* were seen, and a number of highly refractive very long spirochætes with fine and close waving were found, but no organism resembling the *S. pallida*.

"2nd, 3rd, and 4th Memoires of the French Mission to Rio de Janeiro, to Study Yellow Fever."

HEREDITARY TRANSMISSION OF YELLOW FEVER GERMS BY STEGOMYIA.

Marchoux, E., and Simond, P. L. Having proved that infection of *Steg. fasciata* by *Nosema stegomyiæ* is usually effected by heredity, the authors endeavoured to ascertain if the same is the case with the yellow fever germ, and have succeeded in infecting a healthy subject by causing him to be bitten by a female Stegomyia, hatched out from a batch of eggs laid by an infected female. Epidemological facts, however, appear to show that hereditary infection cannot persist through several generations of mosquitoes, and that it plays but a small, though by no means negligible, part in the propagation of the disease. It is obvious, however, that the destruction of eggs and larvæ assumes a new importance in prophylaxis.

We as yet know but little of the conditions that bring about an increase or diminution of the virulence of the virus within the mosquito. May it not be the case that hereditary transmission has an attenuating action? Should further experimentation show that mosquitoes infected in this way communicate only a mild form of yellow fever, it may be important to ascertain if inflammatory bilious fever, which is usually considered to be a form of yellow fever, may not be simply due to this method of communication.

INFECTION OF STEGOMYIÆ BY CONTACT WITH DEAD INFECTED MOSQUITOES.

Three series of experiments were conducted by the authors to ascertain if this is possible, and their results are negative, and larvæ placed in a flask containing dead infected Stegomyiæ developed into adults which showed no sign of virulence.

The authors have often observed that Stegomyiæ avoid parts of the skin fouled with the excretions of patients. If, then, such excretions are virulent, which, however does not appear to be the case, the mosquitoes would not become infected in this way.

It appears that a fairly high temperature is necessary for the development and preservation of the infection within the mosquito after it has absorbed the virus of yellow fever, but the exact conditions of temperature cannot, as yet, be stated.

An orang and a chimpanzee were made to be bitten by infected Stegomyiæ obtained from Brazil, and seven and nine days after both animals showed an elevation of temperature but without other symptoms that could be interpreted as certainly due to yellow fever.

All attempts at infecting animals with cultures made *in vitro* having failed, efforts were made to cultivate the virus *in vivo* within mosquitoes.

Infected mosquitoes were ground up with glucose and physiological solution and fed to Stegomyiæ, which were subsequently made to bite a man. As a result, the subject of the experiment developed a distinct form of yellow fever. It follows, therefore, that infection can be conveyed from one mosquito to another, but only by methods practicable only within the laboratory. It affords, however, a convenient method of producing infected mosquitoes for experimental purposes.

Experiments on the conveyance of yellow fever by mosquitoes of other species than *Stegomyia fasciata* have proved negative. It may be added that in most other species the female dies immediately after laying a first and only batch of eggs, and that this circumstance hardly admits of sufficient time for the virus to develop within her.

The authors have proved that this is the case with *Culex fatigans*, *C. tæniorhynchus*, *C. cocfirmatus*, *Janthinosoma musica*, *Psorophora ciliata*, and *Tæniorhynchus Arribalzagæ*. *Stegomyia fasciata*, on the other hand, can lay six or seven batches of eggs, provided she obtains a feed of blood after each, and, in the free condition, produces on the average two or three batches.

Researches into the life-history of *S. fasciata* showed that it can bite man either by day or by night from the first days of its adult life. After a few days, however, particularly after laying her first batch of eggs, she bites only during the night, and it therefore follows that man becomes infected almost universally during the hours of darkness. A feed of blood is indispensable to the mosquito for the production of eggs.

The authors further give new ideas as to infantile yellow fever; abortive forms of the disease—immunity, relapses, and the endemicity of yellow fever.

For the preservation of specimens of mosquitoes they recommend enclosing the insects in glass cells, the feet being stuck down with Canada balsam.

The abstractor has, however, tried this plan, and found it difficult to prevent the development of moulds on specimens preserved in this way in a warm, damp climate.

In the fourth memoir are given descriptions of the microscopical lesions found in yellow fever, accompanied by some fine coloured plates. They regard yellow fever as a sort of generalised stentosis, all the organs being more or less affected with fatty degeneration. The glands of the skin and intestine, and the epithelial investment appear, however, to always escape. The tissues were fixed in Borrel's liquid, and stained with magenta-picro-indigo-carmin, or fixed in acidified perchloride and stained with hæmatin and orange solution.

"Arch. Inst. roy. de Bacter., C. P.," 1906, p. 127.

THE TRYPANOSOMES OF AMPHIBIANS.

França, C., and Athias, M., found six *Rana esculenta* from the neighbourhood of Lisbon infected by trypanosomes which they identify as *T. rotatorium* (Mayer), but conclude that two species are really included under the name: *T. concalum* or *costatum* (Mayer), with an ovoid, usually fairly broad body, and striated or unstriated with centrosome near nucleus; and *T. rotatorium* (Mayer), with the body more slender, the centrosome placed near the hinder extremity, and a very well-developed undulatory membrane extending the whole length of the body.

Commenting on the paper in the *Bulletin de l'Institut Pasteur*, September 30th, p. 756, Prof. F. Mesnil states his opinion that had the authors examined a larger number of infected frogs they would have met with intermediate forms and would also find forms with the hinder extremity as elongated as the *T. mega* and *micro-karyozeuton* of Dalton and Todd. In any case he regards the constitution of new species as "a little premature."

The diagnosis of these proposed new forms is: *T. undulans*, 30 by 6-9 microns, with broad undulatory membrane and no free flagellum. *T. elegans*, of same length but only 3 microns wide. They have also met with Sergent's *T. inspinatun.*

The authors lay great stress on the globular or retracted forms assumed by the large trypanosomes after issuing from the vessels, the fate of which had already been made out by Danilewsky, and have followed the process in two individuals from the assumption of the globular form to the disappearance of the undulatory membrane and flagellum. They saw one of the two undergo division into eight segments each with its own nucleus, and finally all degenerate, but they were unable to follow the process in stained preparations.

The same observers in the *C. R. S. Soc. Biol.*, T. lx., p. 1108, describe the phenomena of the division of *T. rotatorium S. Str.* from *Hyla arborea.* It takes a rounded form, losing its membranes and flagellum. The blepheroplast and nucleus divide, the former appearing to play the part of a centrosome in the division of the nucleus. This is especially clear in the process of passing from the second to the fourth nucleus stage, although the authors do not state that it is effected by mitosis.

In preparations fixed at once only the initial stages can be found, the other stages being only obtainable in preparations kept five hours between cover and slip previously to fixation.

Original Communication.

RODENT ULCER IN A NUBIAN WOMAN.

By Andrew Balfour, M.D., &c.

Director Wellcome Research Laboratories, Gordon College, Khartoum.

Gentlemen,—In view of the letter from Dr. Branch, of St. Vincent, which appeared in your issue of November 1st, asking if any of your readers have observed rodent ulcer in negroes, the accompanying photographs of a Nubian woman suffering from that condition may be of interest (see Plate).

The patient, who, at the time the photographs were taken, was under the care of Major Bray, E.M.C., was aged about 60, a native of Nubia, and had lived in Egypt for a long time as a slave. She returned to the Sudan in 1901, and went to live at Kodok (late Fashoda) on the White Nile. While there she developed an ulceration at the right side of the root of the nose. This was scraped and healed. A nodule then appeared at the inner canthus of the right eye. The growth broke down and formed a typical rodent ulcer, which at the time the photograph was taken had persisted for one year, and for which the patient refused any treatment. It will be noted that she possessed rather a leprous type of countenance, though there was nothing to indicate that she was suffering from leprosy,

November 21st, 1906.

A BLOOD-SUCKING HEMIPTERON.

By Harold H. King.

Economic Entomologist to the Wellcome Research Laboratories.

As will be seen from the second report of the Wellcome Research Laboratories, the Sudan is by no means deficient in blood-sucking diptera, and since that report has been issued several species, hitherto unrecorded from this country, have been captured. Particulars of these will appear in due course, but in the meantime the occurrence of a blood-sucking insect belonging to a different natural order, viz., *Hemiptera*, seems worthy of notice.

This little bug is one of the family *Reduviidæ*, sub-order *Heteroptera*, and is therefore allied to the Ochindundu (*Phonergates bicoloripes*, Stall.) recorded in the Journal of Tropical Medicine of April 2nd and April 16th of this year, from Angola as feeding on ticks and occasionally attacking man. Up to the present I have been unable to ascertain its species owing to the scantiness of the available literature, but some idea of its general appearance may be gathered from the following sketch and description.

Length, 2·25 by 2·5 microns.

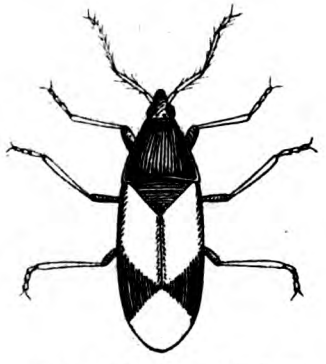
Head black, with posterior margin brownish; compound eyes black; two brown ocelli above and slightly posterior to the compound eyes.

Proboscis three jointed, of medium length, black with a brownish tinge.

Antennæ four-jointed and inserted low on the head. First joint black and slightly swollen; second, longer and tinged with brown; third and fourth, slender, brownish. All, especially the two apical segments, bear hairs.

Thorax greenish black; scutellum of moderate size, black, tinged with brown.

Wings, front pair, basal portion yellowish, a dark triangular patch on the costal border, apical portion membranous, hind pair membranous.



Line | indicates natural size.

Legs, coxæ and femora blackish, trochanters, tibiæ and tarsi yellow; femor a of fore pair swollen; tarsi three-jointed, abdomen black, fringed with pale hairs.

Head, thorax and abdomen sparsely clothed with short, pale, backwardly-projecting hairs.

Most of the members of the family *Reduviidæ* are predacious in habits, preying upon insects, and several species have been noticed attacking man, generally when handled or otherwise molested. I have not seen the young forms of this Hemipteron, but the adult was frequently taken during the evenings of the month of October, biting the hands and wrists without provocation. In captivity, if placed on the hand during the day it would not hesitate to at once plunge its proboscis into the skin and commence to feed, causing a sharp, stinging pain. A small red lump was the only after effect noticed, and this usually soon disappeared.

DENGUE IN EGYPT.

By Llewellyn Phillips, M.D., B.C., M.A.Cantab., F.R.C.S.Eng., M.R.C.P.Lond.

Professor of Clinical Medicine, Egyptian Government School of Medicine, Cairo.

During this past summer and autumn there has been an epidemic of dengue in Egypt, and a large number of cases came under my observation. The earliest cases that I saw were not at all typical, for in several the fever lasted seven to ten days and there was no rash, and I thought they were either influenza or some undescribed form of simple fever; but as time passed they became more typical, severe pains being a marked feature of the cases, and rashes began to appear. In Cairo the epidemic was at its height in September and October, large numbers of officials who returned from leave at the beginning of October

falling victims. Not only did Europeans suffer, but many Egyptians as well.

In most cases the disease ran its course in about a week, the initial fever lasting two to five days. In some instances there was a rigor during the course of the initial fever; the terminal fever, however, was not always noted. In several cases there were very severe pains in the eyeballs, and in some, pain in the testicles. The terminal rash took several forms; whilst many had the typical morbilliform rash starting on the hands and spreading to the body, in others it took the form of an erythematous blush. In two instances I noted typical urticaria, one patient being taken ill with pains and slight fever on a Friday night, on Saturday night a rigor occurred, the temperature falling to the normal at 2 a.m. on Sunday morning. On Tuesday morning, a typical urticarial rash appeared all over the body without a rise of temperature being noted, and lasted about twenty-four hours. In others it took the form of purpura. An Egyptian whom I saw in consultation on the sixth day of his illness had a copious petechial rash over his hands, arms, and chest, and also had hæmorrhages from the nose, stomach, and rectum. The case looked somewhat like typhus, but the temperature was beginning to fall, the mental condition was quite clear, and the patient's appetite was returning. The temperature was normal the next day. I met him out at the Pyramids a few days later, quite well; he was, however, rather weak. In the case of a little Egyptian girl, a few days after the apparent termination of the disease there occurred profuse epistaxis and a copious purpuric rash with vibices, and large blood-stained blebs on the lips. In many instances the secondary rash was absent.

On more than one occasion I saw epistaxis occur as a sort of crisis. Hæmorrhages were a marked feature of the epidemic in Luxor and other towns in Upper Egypt.

In two instances I saw a second attack in the same patient. A young Englishman was taken ill in September with severe pains and fever. These lasted about three days, then he was free from fever and pain for two days, then they both recurred for a day; there was no rash. I saw him again in October with similar symptoms, and this time he developed with the secondary fever a typical morbilliform rash.

I only saw one death. This patient's urine was, however, loaded with albumen, and he died with uræmic symptoms, the temperature running up to 107·2° F., in spite of the application of cold packs.

Thus I observed great variety in the secondary half of the disease, fever occurring without rash, and rash without fever, unless it was so transient as to be overlooked, and neither or both occurring. Lastly, as I have described above, there was a great variety in the rashes. The occurrence of hæmorrhagic forms of the disease is especially noteworthy.

As regards treatment, I found aspirin or salicylate of soda the best means of relieving pain, with, in some cases, local applications. Feeding I did not worry much about, there being in many cases little or no desire for food of any kind, and as long as they took plenty of fluid I was quite satisfied. In some instances there was much vomiting and abdominal pain. For the hæmorrhagic cases and for the urticarial cases I used calcium chloride, which gave much relief in the urticarial cases. When there was much sleeplessness I found Dover's powder useful, but given in a large dose. As much weakness and depression was left behind I used to conclude treatment with strychnine and quinine, or arsenic and iron.

VOMITING SICKNESS OF JAMAICA.

By C. W. Branch, M.B., C.M.

In the Annual Report of the Senior Medical Officer of Jamaica for 1904-5, and again in that for 1905-6, Dr. Errington Kerr refers at some length to a condition there known as vomiting sickness. At his suggestion the Government of Jamaica issued a circular to the other West Indian Governments, asking if such a disease had been observed in other places by the medical men.

Not a Specific Ailment.

After a careful examination of the reported cases and the remarks of several of the Jamaica medical officers, one comes to the conclusion that the vomiting sickness is not a disease *sui generis*, but in part akee poisoning and in part a coterie of pathological conditions characterised in common by the clinical features of vomiting and convulsions.

In several West Indian Islands there is some one disease, so called, to which is popularly attributed all the rapidly fatal cases of illness. In St. Kitts this is the "jaunders," in St. Lucia "pleurisie," with its varieties, "fausse pleurisie" and "pleurisie manquée," in Tortola the "biles." No doubt the vomiting sickness enjoys a similar local reputation in Jamaica.

Course of Illness.

Vomiting sickness usually attacks children; often several cases happen about the same time in a village, sometimes two in the same house at once. It occurs most commonly about January, but also in other months of the dry season. The typical attack has a sudden onset with pain in the belly and vomiting; after a few hours' interval of comparative relief vomiting again begins, and is followed by convulsions, coma and death. The description of the cases, however, shows that there is considerable variation in the features of the fatal illnesses which are instanced as vomiting sickness. In several mention is made of fever. Grave cases are rarely seen by a medical man, and information can only be gathered from the parents. Cases seen in life and diagnosed as vomiting sickness usually recover.

The diseases which most commonly produce the symptoms of vomiting and convulsions in negro children are ascarides and malaria. The few deaths among adults attributed to vomiting sickness are perhaps due to one or other of several acute diseases, as in the case of the "pleurisie" of St. Lucia, for example, pneumonia, bilious remittent fever, and obstruction; some, perhaps, are even due to poisoning. The description of one case, together with the *post-mortem* findings, suggests an epileptic or syphilitic epileptiform seizure.

To illustrate paper by ANDREW BALFOUR, M.D., "Rodent Ulcer in a Nubian Woman."

Post-mortem Appearances.

The *post-mortem* appearances in the cases of vomiting sickness also vary somewhat, though evidences of convulsions seem to be usually present—meningeal hyperæmia, congestion of the choroid plexus, and venous engorgement of the lungs. With regard to the other findings, it may be said that the acute congestion of liver and kidneys was no doubt produced or enhanced by high temperature. The spleen enlarged, firm and congested, suggests malaria. The full bladder indicates coma. No examination of spleen or blood has been made for malaria. One medical officer, it is true, refers to this, with an offer to make such examination if the Government would provide him with a microscope. The authorities do not appear to have availed themselves of this offer, a neglect which is perhaps pardonable, for if the gentleman has waited twenty years for someone to give him a microscope, it may be doubted what use it could be to him now.

No attempt seems to have been made to obtain analysis of the gastric contents, even in cases where suspicion of poisoning might reasonably have been entertained. In the Report for 1905-6 are the details of two *post mortems* made the same day on children of one family who had died of "vomiting sickness." The appearances described are quite inconclusive, and hardly even characteristic of disease, yet the deaths were certified to be due to vomiting sickness, and no effort was made to exclude poisoning.

Mortality. Treatment.

All the observers agree that the mortality of vomiting sickness under treatment is small. But as the same writers profess to be entirely ignorant of the nature of the condition, such treatment as is applied must be empirical and symptomatic. Dr. Tillman, however, who treated 144 cases which he diagnosed as vomiting sickness, with only two deaths, used a most rational treatment. He gave promptly santonin and calomel, followed by a course of quinine. The success of this procedure should have suggested the true explanation of the symptoms. The rest of his treatment is symptomatic.

Ascarides and Malaria.

The District Medical Officers of Jamaica do not attend the labourers children free as part of their official work, as we do in the Leeward and Windward Islands, consequently they have not the opportunity of knowing how much sickness there always is among negro children in their natural state. It is only when attention is attracted by the occurrence of several deaths in rapid succession, that the medical officer may be called upon to investigate and to treat the children in the locality, or supply medicines to the police to treat them. Also the districts are larger and much of the population is remote from a medical man. The peasants are therefore far less accustomed, than with us in the Lesser Antilles, to that medical aid which is deemed a necessity of civilised life. The children are of small value and are readily replaced; to take them to a doctor costs I believe four shillings. At this price it must be extremely rare that a labourer will or can obtain medical advice for a child. With us, on the contrary, the children are frequently brought at the slightest ailment, and demands for worm powders are constant. On the whole, we must therefore have far fewer cases of grave infection with ascaris or malaria. Notwithstanding, we are familiar with "attacks of worms," and "worm fits," as they are called in St. Vincent, which correspond, by description, to much of the vomiting sickness. How much a West Indian population can harbour worms may be gathered from the fact that of 414 persons, mostly adults, of the labouring class, in St. Vincent, I found ova of ascaris in the fæces of 56 per cent. Of children it may be safely said that not one is free of worms unless he has been recently treated.

A Dry Season Disease.

Vomiting sickness is said to be prevalent in the months which constitute the dry season, especially January. Cases of this kind are no doubt always occurring, but they are at this period sufficiently numerous to excite alarm. In the dry season, as several of the observers point out, the people are apt to drink bad water. This means a prevalence of enteritis, due probably to balantidium, cercomonas, or trichomonas, all of which I have observed in St. Vincent in diarrhœas.

The consequent unrest of the worms excites reflex disturbances through the already irritated sympathetic. The general resistance, low before, is still more lowered by the diarrhœa, and these nervous disturbances are manifested as vomiting and convulsions.

Again, the dry season is the time for water-holes and rock puddles in the guts. In the heavy rains there is little opportunity for mosquitoes to breed in watercourses, but in the dry season there are occasional rains enough to fill puddles. It must be borne in mind that convulsions is often the first observed indication of a malarial attack in a child. Vomiting is common in the onset of many fevers. The combination of vomiting, convulsions and coma, with high temperature noted by some of the observers, is strongly suggestive of malaria.

The Akee Tree Fruit.

In Jamaica the presence of the akee tree forms a condition peculiar to that place among West Indian Islands. The white, brain-like interior of the fruit can be eaten raw and has a nutty flavour, though it is usually cooked and makes a delicious vegetable. In the centre, attached to the shiny black seeds and extending into the lobes of the white "meat," is a pink placenta in which is a poisonous principle. These placentas should be carefully picked out of the fruit. The miserable, half-starved piccaninnies gather and eat the fallen fruit ignorant of the fatal pink membrane. The old planters of the island, living among the people and knowing more of them than do the medical officers, can give some account of the frequency of this accident.

Business Notices.

1.—The address of the JOURNAL OF TROPICAL MEDICINE AND HYGIENE is Messrs. BALE, SONS & DANIELSSON, Ltd., 83-91, Great Titchfield Street, London, W.

2.—All **literary communications** should be addressed **to the Editors.**

3.—All **business communications** and **payments,** either for subscriptions or advertisements, should be sent **to the Publishers** of the JOURNAL OF TROPICAL MEDICINE AND HYGIENE. Cheques to be crossed The Union Bank of London, Ltd.

4.—The Subscription, which is **Eighteen Shillings** per annum, may commence at any time, and is payable in advance.

5.—Change of address should be promptly notified.

6.—Non-receipt of copies of the Journal should be notified to the Publishers.

7.—The Journal will be issued on the first and fifteenth day of every month.

Reprints.

Contributors of Original Articles will be supplied FREE with six copies of the Journal if a request accompany the MS. If reprints are required they will be supplied by the publishers, if the order is given with remittance when sending the MS. The price will be as below:—

50 Copies of four pages, 5/-;
100 ,, ,, 6/-;
200 ,, ,, 7/6;
50 Copies beyond four up to eight pages, 8/6;
100 ,, ,, ,, 11/-;
200 ,, ,, ,, 14/6.

One page of the Journal equals 3 pp. of the reprint.

If a printed cover is desired the extra cost will be for 50 Copies, 5/6; 100 Copies, 6/6; 200 Copies, 7/6.

THE JOURNAL OF

Tropical Medicine and Hygiene

DECEMBER 15, 1906.

THE HOUSING OF EUROPEANS ON THE WEST COAST OF AFRICA.

IN the bad old times, which ended with the last century, the special plague spot of the West African town of Lagos was a certain marshy tract known to Europeans as the Kimberley swamp. Its position was such that it was obviously the most urgent danger to the health of the town, and its reclamation was the first great work of anti-malarial sanitation undertaken by that great and scientific administrator, the then Governor, Sir William MacGregor. During his only too short period of rule, anti-malarial sanitation was rigorously pushed, and the effects of his wise and effective action are shown more and more plainly every year in the health statistics of the colony, the deaths from malaria having fallen from 4 per cent. for the period 1897 to 1900 to 1.5 per cent. for the first five years of the present century. Since 1902, in fact, there has been only one fatal case of malaria, so that though there is undoubtedly much room for improvement; the benefits that have resulted from anti-malarial measures are absolutely beyond question, for the change from a pestilential mortality of 40 per *mille* from malaria alone to the comparatively moderate present death-rate was abrupt, and has been continuously maintained.

With such triumphant results, it might be thought that the policy so happily inaugurated by Sir W. MacGregor would be pushed and extended by any body of reasonable men, but this does not appear to be the case unless the following allegations can be called in question.

The Kimberley swamp was very properly converted into an open pleasure ground, but it should be needless to point out that it could never become suitable for an inhabited site, as the level of the subsoil water must necessarily always remain perilously near the surface, and the sanitary objections to the occupation of sites on made ground are so well known that such a course would never be permitted in the most backward municipality in England, and in the tropics, the dangers of such sites are many times multiplied. It appears, however, to be a fact that the Local Government have actually erected quarters for European officials on the edge of this site, and are contemplating building more. The avoidance of such situations is so much a matter of the A B C of sanitary science, that it is impossible to believe that the Government can have consulted their medical officers on the matter, as to do so would be to assume a degree of ignorance on the part of the latter that is quite incredible at the present day.

Further, the bungalows in question are absolutely unsuited for the purposes of tropical residence, being planned with the usual toy verandahs, which render the provision of adequate ventilation out of the question, as to do so would involve the admission of the direct rays of the sun to the rooms for a considerable portion of the day.

It may be taken as axiomatic that the verandahs of European quarters should never be less than 12 ft., and the more that can be afforded over this the better.

In a climate such as that of the West Coast, the first essential of health and comfort is a large roof area, and provided this be sufficiently extensive, the more nearly the house resembles a bird-cage the better. In any case, the walls should be placed so well inside the area of shade cast by the roof, that the sun can never shine directly on them after it is a few degrees above the horizon.

Given these essentials, it is easy to plan doors and windows of sufficient size to admit a pleasant and healthful current of air, in spite of the wire gauze mosquito guards, which we know to be an absolute essential of safety in a mosquito-ridden country.

An ideal residence should be protected with adequate gauze-guarded verandahs on all sides, but in any case, one verandah and the dining and sleeping room should be so provided, and the verandah enclosed with wire should be that on which the sun falls least throughout the year, so that it can be used for living and working in throughout the day, which is of course impossible in the absurd apologies for verandahs that are only too common on the "West Coast." But even worse remains, for, bad as malaria is, dysentery is worse, and dysentery is undoubtedly a water-carried disease. As in most parts of the West African littoral, the water supply is one of the most formidable dangers and difficulties in Lagos, the residents having to depend on surface wells. These wells are in no case above suspicion, and it is to be feared that the best is not made of them by adequate measures of protection;

but in the case of the new quarters in question, the wells have been sunk into the fathoms-deep organic filth of the old malarial marsh.

Of course, malaria cannot be conveyed in this way, but the consumption of such water is a well-known source of dysentery, and we shall be agreeably surprised if the unfortunate officials so supplied do not furnish a new instance of the danger of ignoring a commonplace of tropical sanitation.

It is wrong and immoral for any corporate body to subject its employees to needless risks, and if the local authorities do sufficiently realise this, surely a government which professes to concern itself so deeply with the housing of the working classes should step in and insist on the equally fair treatment for those who are bearing "the white man's burden" in our distant colonies and dependencies, by insisting on their being housed so as to be able to carry on their arduous and thankless duties under the best attainable conditions of health and therefore of efficiency. The reverse policy of stinting expenditure on the building of suitable and healthy quarters is, moreover, not even defensible from the financial point of view, as its penny wisdom inevitably results in a pound folly of needless ineffective charges to pay the salaries of officials on sick leave, who would have remained fit for work under a more enlightened *regimé*.

LIVERPOOL SCHOOL OF TROPICAL MEDICINE, MEMOIR XXI., SEPTEMBER, 1906.

The Runcorn Research Laboratories of the Liverpool School of Tropical Medicine.

These laboratories are situated at Crofton Lodge, Runcorn, sixteen miles from Liverpool, where stabling and pasture for all sorts of animals is obtained. An important function of the laboratories is to supply living parasites for the practical instruction of students taking the course in tropical medicine at the Johnston Laboratories, Liverpool. At Runcorn the various trypanosomes, spirochætes, the ticks *Ornithodoros moubata*, *Argas miniatus*, *Ixodes reduvius*, and *Rhipicephalus annulatus* are kept "a-going" and utilised for teaching purposes.

An Experimental Study on the Parasite of the African Tick Fever (Spirochæta Duttoni). By Anton Breinl and Allan Kinghorn.

The parasites experimented with were brought from the Congo Free State in infected ticks to Liverpool, and the strain was recovered from monkeys which had been infected through their bites. (1) It was soon shown that the spirochætes of tick differ from the *Spirochæta obermeieri* of relapsing fever, and the name *S. duttoni* was given to the tick fever spirochæte. (2) The technique of the experimental methods is given; and (3) a description of cases of African tick fever in whites. (3*a*) The experiments on animals show that the blood of patients suffering from relapsing fever is infective for susceptible animals during the periods of apyrexia. (4) A clinical comparison of African tick fever and European relapsing fever reveals the truth of Koch's statement that the attacks in tick fever are shorter than in the relapsing fever of Europe, and that the spirochætes are present in fewer numbers in tick fever. The length of intervals and the number of relapses in tick fever are not yet determined. (5) In experiments to determine animal reactions of *S. duttoni* it was found that monkeys, dogs, horses, goats, sheep, rabbits, guinea-pigs, rats, and mice were capable of inoculation. The most susceptible animals are white rats, and then monkeys. Of the monkeys, the order of susceptibility was as follows:—Young mona (*Cercopithecus mona*) and young Callithrix (*Cercopithecus callitrichus*) were most susceptible, followed by Rhesus (*Macacus rhesus*), "sooty" (*Cercocebus fuliginosus*), "Jew" (*Cercopithecus ?*), and baboons (*Papio anubis*); all the monkeys, with a single exception (a rhesus), became infected. In some animals the parasites were found only in the subinoculations. Cats were entirely refractory to infection. (6) *Chronicity.* Tick fever runs an acute or chronic course; in one case recorded the patient became ill in February, and the last relapse took place on April 22nd. (7) *Virulence.* No difference in virulence was noted in strains which had passed through a long series of animals, and that derived from animals directly infected through tick bites. The numbers of spirochætes in animals experimented upon varied directly with the number present in the inoculating blood. (8) *Immunity.* No satisfactory explanation has yet been given of the disappearance followed by a reappearance of the spirochætes in the blood. There was shown to be a relatively active immunity against reinfection, as animals reinoculated at various intervals after recovery up to seven and a half months did not become infected at all, or only had a very slight attack. Treatment by horse, monkey, and rat sera showed that hyperimmune serum derived from any one of these animals does not prevent the infection, but it positively lengthens the incubation period and mitigates the course of the disease when given in large doses. No cure was effected by the immune serum. Experiments show that there is a slight degree of inborn immunity, which speedily disappears, however. (9) *Specific nature of S. duttoni.* The spirochætes of African tick fever is of a species differing from *S. obermeieri*, since each confers a relatively active immunity against itself, and not against each other. (10) *Placental transmission.* The *S. duttoni* has been shown to pass through the placenta from the circulation of the mother to that of the fœtus, and that the majority of fœtuses carried by infected mothers are themselves infected. The parasites in the fœtus are fewer in number than in the mothers; they show no morphological change after gaining the fœtal blood, nor does the mother abort. An interesting observation noted was that although the infected fœtuses were born and lived, fewer reached maturity than in the case of healthy rats. (11) *The spleen in spirochætal infection.* (*a*) Experiments showed that the course of tick fever in animals from which the spleen had been removed does not differ from that noted in normal animals. The spirochætes appear in the peripheral circulation, increase in numbers to the maximum, then decrease and disappear from the blood. After an interval the

cycle is repeated. (*b*) It was shown that the spirochætes, when disappearing from the blood, do not rest solely in the spleen. (*c*) Spirochætes are present in the peripheral circulation in an infective stage on the first day after ticks are fed on a susceptible animal. (*d*) After recovery from the disease, animals subjected to splenectomy reacted in the same manner to reinoculation as did the controls. (12) An infective stage of *S. duttoni* is capable of passing through a Berkefeld filter, which does not allow the passage of *Bacillus prodigiosus*. (13) No definite conclusion has as yet been arrived at concerning the morphology of *S. duttoni*. (14) In experiments concerning the protozoal nature of spirochætes, Dutton and Todd state that the transmission of the spirochætes by ticks is not merely mechanical, and that some developmental process takes place in the tick. The passage of the spirochætes from the alimentary canal of the ticks to the ovary and eggs is interesting, and it has not been shown to occur in the case of any bacterium up to the present, but is known to occur with protozoa. (15) The animal reactions of *S. obermeieri* are quite different from those of *S. duttoni*, and, contrary to Novy and Knapp's statements that a relapse has never been seen in rats, Breinl and Kinghorn show that if the examination is continued for a sufficiently long period relapses do occur. (16) Animals which have recovered from infection by *S. obermeieri* acquire a certain amount of active immunity against reinfection, the efficiency of which corresponds directly to the severity of the attack.

Abstract.

Paratyphoid Fever and Typhoid Fever.

By Lieut.-Colonel D. B. Spencer, I.M.S.

Lieut.-Colonel Spencer, in a series of articles published in Mauritius (1906), deals with paratyphoid fever and enteric fever in India. He defines the ailment as follows :—

Paratyphoid Fever.—Definition.

Bacteriologically, judging from what I have read of the subject, I should say it is a fever caused by one or more members of the typho-coli group of organisms acting either singly or collectively ; that is to say, more than one organism of the typho-coli group probably take part simultaneously in the causation of the disease by a process known in bacteriology as symbiosis. But it must be clearly understood that this fever is not caused by the bacillus typhosus, the *causa causans* of true typhoid fever, for the Widal reaction, with a culture of the *B. typhosus*, is always negative in paratyphoid fever, and it is this fact which has drawn the attention of different observers in different parts of the world to this fever. It has been observed in America, England, Germany, France and India, so that the disease may therefore be said to have no geographical limits.

Bacteriology of Disease.

So far as I can gather from current literature on the subject it appears to me that paratyphoid fever is caused by the group of bacilli known as the Gaertner group, which occupy an intermediate position between the *B. typhosus* at the one end of the chain and the *B. coli communis* at the other end.

One of the most important organisms of this Gaertner group is the *B. enteriditis*, which is the bacillus usually associated, I believe, with meat poisoning and ptomaine fever, and it is this bacillus which is generally credited with being the cause of paratyphoid fever. According to Dr. Row, of Bombay, the *B. coli communis* is not an unimportant factor in the causation of paratyphoid fever.

Intestinal and Sewage Bacteria.

A large number of different kinds of bacilli have been isolated of late years from crude sewage, of which the following, I believe, are fairly well-known varieties :—*B. coli communis*, with about 150 varieties ; *B. cloacæ fluorescens*, *B. stercoralis*, *B. frondosus*, *B. fusiformis*, *B. subtilis*, *B. subtilissimus*, *B. mesentericus*, *Proteus cloacinus*, *Proteus vulgaris*, several other species of *Proteus*, *Micrococcus aurora*, *B. enteritidis sporogenes*, of which, according to Klein, there are from 500 to 600 spores per cc. of sewage ; then there are the thermophylic bacteria, of which there are some eight known varieties, and lastly we have the great streptococcus and staphylococcus families with their numerous varieties. These bacteria probably get into the human intestinal canal, for with every drop of water that we drink and with every particle of food that we eat, an immense number of bacteria enter the stomach, and although, fortunately for us, most of them are dissolved in the acid juice of the stomach, it is reasonable to infer that in the struggle to escape some of these bacteria find their way into the intestinal canal and are finally passed out with the fæces.

It is possible also that these same harmless organisms, under a new environment in the human intestinal canal, may have sometimes a share in the causation of paratyphoid fever by a process known as auto-infection or auto-intoxication from the intestinal canal.

In a paper on Paratyphoid, by two French doctors, Saquepée and Chevral, published lately in *La Presse Medicale*, the following statement occurs :—

"Two types are generally recognised, A and B. The cultures of A on gelatine, potato and agar resemble those of typhoid, while those of B are more luxuriant and recall coli cultures. Type A acidifies milk quickly and definitely (one to three days). Type B (alkalifaciens of School Muller) causes in the same media a transient acidity replaced later by a more pronounced alkalinity. Both types are very pathogenic to laboratory animals."

It will appear from the above description that paratyphoid bacilli, like the Gaertner group, occupy an approximately intermediate position between the *B. typhosus* and the *B. coli*, and they may therefore be said to be a branch if not a part of the Gaertner group.

Enteric Fever in India.

Why are the natives of India apparently immune to enterica ?

In this connection, I think, the chemistry of

ptomaines furnishes an important light. We know that these ptomaines are alkaloidal substances of the aromatic series of organic compounds, and that they are formed in the process of putrefaction of proteids or albuminoids derived from nitrogenous animal food, such as meat of any kind. We know also that meat is a regular article of diet for the British soldier, while in the native army a large number (Hindoo) never touch meat, fish, or eggs. Broadly speaking, the food of the British soldier consists largely of animal diet, that of the native soldier of vegetable diet (atta, rice, dal) and ghee, a carbohydrate. Again, beer is a common drink with British troops, and a British soldier can drink as much canteen beer as he likes. In the native army beer is unknown. Now beer is a thing which is very apt to ferment, especially in hot weather, and beer is drunk by British soldiers, in both hot weather and cold, without any restriction.

True Enterica.	Indian Enterica (A Fever with Enteric Symptoms).
Etiology. — *Bacillus typhi*, Eberths' associated with sewage contamination of food or drink.	*Etiology.* — Probably the *Bacillus coli* associated with fermentation and putrefaction of intestinal contents and consequent auto-infection.
Widal Test. — Positive reaction with the *Bacillus typhi.*	*Widal Test.* —Not known. (*a*)
Mode of incidence.—Usually in an epidemic form.	*Mode of incidence.*—Usually in a sporadic form.
Mortality per cent.—7·14 in the last Maidstone epidemic (Poole's Report).	*Mortality per cent.*—About 25 per cent. in India.
Chart.—Often typical. First week, gradual rise. Second week, high continued fever. Third week, gradual defervescence.	*Chart.*—Generally irregular.
Mode of onset.—Gradual.	*Mode of onset.*—Sudden or gradual.
Rash.—Generally present 88 per cent in the last Maidstone epidemic (Poole's Report).	*Rash.*—Generally absent.
Typhoid state.—Early and pronounced.	*Typhoid state.*—Often vague or altogether absent.
Abdominal symptoms.—Whether early or late they are unmistakeable.	*Abdominal symptoms*—Often absent.
Post-mortem appearances.—Typical ulceration of glandular structures of small intestine.	*Post-mortem appearances.*—Often the ulceration of intestine is irregular and extensive, being not confined to glandular structures.
Duration of fever.—Generally three weeks.	*Duration of fever*—Three to four weeks, but it can be aborted by a specific treatment. (*b*)
Treatment.—The recognised treatment has been an expectant treatment with intestinal antisepsis and irrigation (Burney Yeo).	*Treatment.*—The treatment I adopt is an eliminative treatment combined with intestinal antisepsis and irrigation.

(*a*) Now known to be negative.

(*b*) Instead of three to four weeks I should now say from two to eight weeks, or even longer.

Published in April, 1900, in the *Indian Medical Gazette.*

We have thus, I think, in meat and beer those elements of putrefaction and fermentation which are essential for ptomaine formation. The fact that enterica is so much more common in the hot weather than in the cold, *i.e.*, at a time when bacterial activity is greatest in the processes of decay, lends additional colour to this theory, and much of this striking difference in the rates of incidence of the disease between European and native troops is, I believe, due to a difference in diet of the two races.

Summarising the points dealt with in his paper, Lieut.-Colonel Spencer remarks in conclusion: It is, I think, difficult to believe that defective sanitation is the sole cause and the whole cause of enteric fever as seen in India. For, while on the one hand we can, in India, but seldom prove a causal connection between the disease and sewage contamination of food or drink, there is, I think, on the other hand, a vast array of positive evidence to show that a *fever with enteric symptoms*, closely simulating true enterica, (see tables) has been, and can be caused by other factors—factors which I believe are as yet not sufficiently recognised. Although spasmodic efforts have been made from time to time by a minority of original thinkers to show that they do exist, it may reasonably be asked whether, with our advancing knowledge of the subject, the time has not come for medical men in India, whatever may be their past or present convictions, to consider both individually and collectively the various points enumerated above. It is incumbent upon us to set to work to attempt to decide whether the disease we call "enteric fever" in India is always one disease arising from one cause only, or a complex disease presenting several phases and arising from a variety of causes; chief among these may be mentioned climate, food, and intestinal intoxication from fermentation and putrefaction of intestinal contents and the consequent formation of ptomaines and toxins therein of bacterial origin, though quite independently of the typhoid bacillus. For it must be obvious that, without correct premises, without a correct conception of the disease, and without an absolute unanimity among medical men as to what constitutes a correct conception of the disease, the inferences must be wrong and that there never can be any satisfactory solution of a complex and difficult subject like the enteric question.

Tropical Dysentery.—Abstract of paper in *Lancet*, of December 1, 1906, by Captain R. J. Blackham, D.P.H.R.C.P.S.Lond., Royal Army Medical Corps.

Amongst the diseases of special interest to the physician practising in the Tropics, the group of morbid conditions, known by the term of "dysentery," ranks only next in importance to enteric fever. Unfortunately, as Manson points out, our knowledge is not in proportion to the importance of the subject, and in the latest monographs on the disease it is evident that considerable doubt exists in the minds of eminent climatologists, who have made a special study of the malady, as to the exact boundary line between simple diarrhœa and dysentery. It is, however, only in very recent years that the difficulty of diagnosing dysentery has become appreciated, and a few years ago writers used to describe what is now considered to be a group of diseases as a well-defined malady and give its etiology, symptoms, and pathology in precise

terms. It would be well, therefore, to start by defining what we mean by "dysentery," and the definition suggested is that "dysentery is an inflammation of the large bowel, associated with pain, tenesmus, some slight pyrexia, and a large number of stools, consisting of mucus or mucopus, with micro-organisms but with or without blood." I think the last phrase is important, in view of Dopter's work during the past year, and the evidence which he has submitted that simple diarrhœa may be an abortive form of dysentery, and that all cases of acute diarrhœa occurring where dysentery is prevalent should be regarded as suspicious, and, where possible, bacteriological methods resorted to for diagnosis in preference to the rough-and-ready test of the character of the stools.

In the classification of the varieties of dysentery much difficulty and confusion of ideas have arisen, and as Firth points out, "it is doubtful whether the literature of any disease is more encumbered with a mass of names indicating the nature of the disorder or the author's conception of its pathology than is that of dysentery." Terms founded on a pathological basis such as "catarrhal," "ulcerative," and "gangrenous" have been passed on from text-book to text-book and are used by Manson, Scheube, and even such a recent text-book on pathology as Stengel's (p. 547), and in an article just published in the *Lancet*, but as was pointed out by Taylor as far back as 1901, the "disease is essentially the same in all varieties." Such terms merely indicate clinical conditions found in the various stages of a single pathological process, and it would be well, therefore, to dismiss this older classification and adopt the one now used by Osler, namely, (1) amœbic dysentery; and (2) bacillary dysentery. This nomenclature was, I think, first suggested by Davidson, but he added to it a third variety, which does not really exist, as his "dysentery of war" is simply a form of bacilliary dysentery.

Causes of Dysentery.—In considering these we must sub-divide the heading into (*a*) predisposing causes; and (*b*) exciting causes. Let us first consider the causes which predispose to the disease. We find that these fall under four chief divisions, namely, (1) age, (2) sex, (3) occupation, and (4) conditions of lowered vitality.

(1) Age.—Dysentery may occur at any age, but in my experience it has a singular predilection for the extremes of life, children and old people being peculiarly liable, the former, doubtless, on account of their well-known liability to catarrh of the intestinal mucous membrane which is itself a predisposing cause of the disease, according to Scheube (p. 466).

(2) Sex.—According to most authorities this does not exert any influence, but Scheube cites pregnancy as a predisposing cause, and it is within the experience of most physicians who have lived in the Tropics that when dysentery occurs in a pregnant woman, or during the puerperium, the prognosis is very grave indeed.

(3) Occupation.—Davidson asserts that agriculturists are attacked more frequently than persons whose calling is carried on indoors, and according to Lancarol persons who labour in the heat, such as stokers, cooks, and mechanics, are peculiarly liable to disease.

(4) Conditions of lowered vitality.—There can be no doubt that in conditions of health the pathogenic organisms of dysentery, enteric fever, cholera, and other diseases pass through the intestinal tract in association with the luxuriant flora and fauna which normally flourish therein, without causing any inconvenience, and that it is only when the mucous membrane of the bowel is the subject of some inflammation, irritation, or impaired nutrition that it forms a suitable nidus for the *Amœba* or *Bacillus dysenteriæ*.

Such conditions of reduced vitality may be induced by a variety of circumstances, first and foremost among which I would place "chill," which Manson declares to be a "powerful excitant of dysentery," and Scheube considers, above all things, to be mentioned as a predisposing cause. Next I should place "unfavourable hygienic conditions," such as overcrowding, contamination of the soil with sewage, and an impure water supply. Epidemics of the disease are therefore peculiarly likely to occur in war and as an accompaniment of famine, and Scheube says, "In almost every long campaign or siege the outbreak of an epidemic of dysentery amongst the combatants, amongst the besiegers as well as the besieged, is a common occurrence."

Amœbic Dysentery.—This variety is essentially slow developing in its nature, although acute attacks are not uncommon. It is styled by Firth and others "endemic dysentery," and it appears to have little tendency to break out into definite epidemics, as is the case with the other form of dysentery. An amœba was first described by Lambl in 1859 and subsequently by Löseh in 1875, but to Schaudinn is due our present exact knowledge of the genuine organism. He found that many kinds of amœboid organisms occur in the human intestine and that some of these are not true amœbæ at all but merely amœboid stages in the development of the higher forms of the protozoa such as trichonomas, lamblia, and other infusorians. Genuine amœbæ he divided into two classes: (1) those provided with a shell, the thecamœbæ; and (2) those that have no other covering, or gymnamœbæ. "At least one of the former and two of the latter sort are now known to occur in the intestine." The two naked forms are genuine parasites, but one of them is harmless and the other one of the most dangerous of pathogenic protozoa. Schaudinn has re-named the former, hitherto known as the *Amœba coli*, *Entamœba*, and the latter, hitherto known as the *A. dysenteriæ*, as the *Entamœba hystolytica*. The *E. coli* was found in from 20 to 60 per cent. of healthy stools by Schaudinn and is a shapeless mass of protoplasm not showing much differentiation into ecto- and endoplasm but possessed of a well-marked nucleus. It is difficult to find in healthy fæces, as its habitat being in the upper regions of the colon it dies out as the intestinal fæces become firmer on their passage down the bowel. If, however, the downward course of the fæces is hurried by saline purgatives the amœbæ can be readily detected, as Schuberg has shown. "The amœbæ have two distinct cycles of development; one vegetative or asexual, taking place in the naked state, the other displaying a

primitive but unmistakeable form of sexuality and occurring inside of a capsule resembling an egg-shell and termed a cyst. In the vegetative form the amœbæ either simply split in two or their nucleus divides into eight daughter nuclei, each of which takes a portion of the protoplasm so as to form a characteristic brood of eight young amœbæ, which come apart. In the other or sexual cycle the amœba rounds itself off, comes to rest, and contracts and surrounds itself with a gelatinous coat which becomes the cyst wall. The two nuclei, after undergoing reconstruction and chrosmosomic reduction, divide into halves, which copulate, so as to form two fresh nuclei, each containing half of the two parent nuclei. Each of these copulation nuclei now divides twice and the divisions form eight young amœbæ which, however, cannot leave their cyst until it has been taken in by a new host and has had its wall softened in the stomach and duodenum." The pathogenic *E. hystolytica* differs materially from the foregoing. It possesses a tough ectoplasm which enables it to force its way between the layers of the mucous membrane and produce the undermined ulcers of tropical dysentery. Schaudinn has actually observed the organism in scrapings of the bowel from an experimentally infected cat. "The two sorts of amœba differ also in their reproduction. The pathogenic form in its vegetative stage divides into two, or forms new individuals by budding. Brood formation does not occur. The process of encystment is also quite different. It comes on when the patient is beginning to recover from his attack of dysentery and the fæces are becoming solid. The nucleus gives up most of its chromatin in granular form to the plasma and its remains are expelled. The plasma now projects from its surface a number of little knobs, each containing a particle of chromatin and measuring from three to seven micra in diameter. These break off after a while and each becomes surrounded by a capsule which ultimately becomes quite brown, hard, and opaque. These 'spores' are then expelled with the fæces and serve to infect a fresh host."

McWeeney states that so far back as 1902 he believed that the *A. coli*, or rather, I presume, what we now know as the *E. histolytica*, was causative of one form of dysentery, and in the very excellent paper from which I have quoted above he holds that "one of Schaudinn's experiments seems quite conclusive." In this experiment this great investigator, whose untimely death we all deplore, dried a small quantity of fæces from a case of undoubted dysentery in air, and satisfied himself microscopically that it contained no cysts of *E. coli*, but only the small brown spores of *E. histolytica*. The cover-glasses were then removed from the slides actually examined, and the fæces washed off with about one cubic centimetre of sterile water and administered in food to a young cat whose stools had been proved to be free from amœbæ. Three days later the cat began to pass slimy fæces streaked with blood. These were found to be swarming with typical *E. histolytica*. Next day the animal died from dysentery. The necropsy showed characteristic ulceration of the large intestine with crowds of amœbæ in all stages of penetration into the intestinal wall. Schaudinn administered quantities of the fæces of this cat to another, but it remained healthy. He then gave a small quantity of the dried fæces originally used, and within six days amœbæ appeared in the fæces. This cat, which was older and stronger than the first one, developed dysentery, and "died in about a fortnight" From this experiment it would appear that amœbæ taken by the mouth appear to be harmless, and that "it is to the dried-up, cyst-containing fæces present in dust and water that we must look for the propagation of dysentery."

Bacillary Dysentery.—Although it is evident from the foregoing that the *A. dysenteriæ* is clearly the exciting cause of many cases of dysentery, it is equally evident that there is a very large amount of dysentery which is not due to amœbæ. In support of this we find that Bruce, Washbourn, and Birt failed to find amœbæ at all in the large number of cases they examined during the South African epidemics. Major W. W. O. Beveridge discovered amœbæ in only three out of 147 cases examined in the Army Medical Service laboratories at Pretoria. Strong and Musgrave noted 766 cases of bacillary to 561 of amœbic dysentery in their investigations in Manila, while Rogers states that the bacillary is much the most common form of the disease in Calcutta. The credit of first recognising a definite bacillus which was capable of producing dysentery is due to Chantemesse and Widal, who showed by experiments on animals that a bacillus closely allied to the *B. coli communis* was frequently present in the stools of epidemic dysentery, and capable of producing the disease in cats; but the question of the exact form of bacterium responsible for the disease was hotly disputed until Shiga, of Tokio, isolated a bacillus from the type of disease occurring in Japan, and "proved its specificity by demonstrating the agglutination of its cultures by blood serum."

Prevention of Dysentery.—(1) General. Scheube states that the general prophylaxis of dysentery demands careful attention to general hygiene and the personal avoidance of the predisposing causes, and goes on to say "The circumstance that dysentery does not now appear in the tropics with the same frequency and severity of thirty or forty years ago is to be ascribed to the improvement in hygienic conditions, especially in regard to water-supply, which has taken place during recent years and to the more rational method of treatment practised by the doctors of the present day. In order to prevent the disease spreading the intestinal evacuations should be disinfected, as should also night commodes, utensils, privies, &c., as well as the soiled linen and bed-linen used by the sick." He further recommends that when constipation occurs in the East only mild aperients should be taken, and quotes, without comment, the advice of Lancarol to take cold baths throughout the year as a prophylactic. To prevent dysentery in the tropics I would suggest that the following rules be strictly adhered to, and that, having themselves grasped their importance, all officials should be induced, by precept and practice, to enforce obedience to this simple code on their subordinates. (1) Drink only boiled or preferably sterilised water, by which I mean water not bacteriologically sterile but which has been

heated to 80° C., a temperature which is sufficient to kill non-spore-bearing organisms and certainly the bacteria of dysentery, cholera, enteric fever, and most other communicable diseases. (2) Clothe warmly, and wear a so-called cholera-belt to avoid chill being communicated through the abdominal wall to the intestine. (3) Be temperate in food and drink, and remember that alcohol is a luxury and not a necessity of life, especially in the tropics. (4) Seek medical advice at once when constipated or suffering from diarrhœa, however mild in character, and avoid drastic cathartics. (5) Isolate all cases of dysentery rigorously, regard cases of diarrhœa occurring during epidemics as suspicious, and disinfect with care all diarrhœic stools and the bedding and clothing of all persons affected with dysentery or suspicious diarrhœa [15].

Treatment of Dysentery.—We are confronted at the outset with a serious difficulty. We find that the treatment of the two varieties of the disease is hopelessly mixed up by each and every authority, even in the most recent articles on the subject such as that of Dr. C. B. Sheldon Amos, and that it is almost impossible to differentiate the remedies which are to be recommended in the variety due to amœbæ from those suggested for the bacillary type of the disease. As, however, it must frequently be impossible in practice to decide the type of disease at the outset of treatment it will, I think, be best to discuss the therapeutical measures available as a whole and merely to divide our remarks under the classical headings of "acute" and "chronic."

The indications which will assist us in the treatment of dysentery are five in number: (1) To relieve the pain and tenesmus; (2) to avoid all irritation of the inflamed mucous membrane; (3) to promôte intestinal antisepsis by removing foul accumulations and arresting putrefaction; (4) to counteract any morbid agency in the blood as far as may be; and (5) To support the patient's strength by suitable diet. Let us consider these indications.

Firstly, to relieve the pain and tenesmus.—As the use of opium has been unhesitatingly condemned by the older writers in the treatment of acute dysentery, the evidence of Washbourn and Faichnie is of value as expressing the most recent views on the subject. Washbourn goes so far as to say that he has seen lives saved in South Africa by the introduction of a morphine suppository, so there is now no doubt that the first indication of the treatment of acute dysentery is to give opium in some form or other, not to act as an astringent but simply to moderate and control the painful contraction of the intestines which produces what is known as tenesmus.

Secondly, to avoid irritation of the inflamed mucous membrane. In this relation I may point out that many years ago Sir William Gull summed up the treatment of acute dysentery in three words, viz: "Rest, warmth, and ipecacuanha." This was not only smart and epigrammatical but it had the advantage of being correct, and Washbourn after his exceptional experiences in South Africa, has little to add to the aphorism of the great Gull. To avoid irritation of the inflamed mucous membrane we must apply the first two of Gull's trinity of remedies. Rest is absolutely essential, and in all cases the patient should remain in bed and use a bed-pan. All foods which leave a residue prone to decomposition must be avoided, and Manson objects even to milk in acute dysentery if the tongue is foul, and limits the diet to weak chicken broth, barley, and rice water, with a little egg albumen till the tongue cleans. Milk is, however, considered the best food in all cases by Scheube and Yeo, while Osler recommends "milk, whey, and broths."

The third indication for treatment is to attempt to produce intestinal antisepsis. This can, of course, be merely an attempt, as the bowel may be regarded as a forest crowded with flora and fauna of the most varied and septic character, but although it may be useless to try to render the mucosa aseptic, it may be possible to place it in a position which will discourage the growth of a delicate organism such as the bacillus of dysentery appears to be. There are three ways in which we may attempt to treat this indication—namely: (1) by saline aperients which sweep all foul accumulations and organisms from the intestinal tract in a more or less mechanical manner; (2) by the administration of certain drugs said to be specific; and (3) by washing out the bowel per anum by means of astringent and antiseptic fluids. In the tropics the best preliminary treatment for all kinds of diarrhœa is a dose of castor oil with or without from 15 to 20 minims of liquor opii sedativus, and Manson believes that slight cases of dysentery are often checked thereby and require no further treatment except rest and a bland non-irritating diet for a few days. Having done this the physician must elect whether he will resort to the saline, specific, or lavage method of treatment.

"Specific" Treatment.—Scheube says: "The principal drugs used in the treatment of dysentery are calomel and ipecacuanha, the effects of which do not depend solely on their aperient and emetic qualities. The drugs must be regarded as having a 'specific' effect, a fact which does not seem as yet to have been fully acknowledged, at least as far as German text-books are concerned." Manson says he can offer no explanation of the action of any drug in dysentery, and admits that we use them empirically, but thinks that "ipecac. and simaruba really seem to have some sort of specific action on the disease or its cause, but in what way it is impossible to say." Yeo thinks that ipecacuanha may be microbicidal and arrest the growth of the organism, whether amœba or bacillus, producing the disease, while Fayrer points out that the mortality of all varieties of dysentery in India, which was 11 per cent. before its use, fell to 5 per cent. after its introduction. The method of exhibiting the drug almost universally adopted in military practice in India, is to interdict food for three hours and then to give 20 minims of liquor opii sedativus in a small quantity of water. Half an hour after the opium 30 grains of powdered ipecacuanha are given in the form of freshly prepared pills or as a bolus. To prevent vomiting the patient is directed to lie perfectly still in a darkened room and not to drink, speak or move for three or four hours. He must be cautioned not to swallow his saliva, and a nurse should remain by his side with directions to wipe away any salivary secretion on the slightest indication from the patient.

Ipecacuanha prepared without the emetic principle was much vaunted at one time, but its use was abandoned by most Indian practitioners before the South African war, when it was extensively used and found most unsatisfactory. I believe Day's remarkable experience of the failure of the drug to cure dysentery was due to his using this preparation He reported sixty cases, in twenty-six of which he used ipecacuanha *sine emetina* and opium, with the result that nine died, and thirty-two in which he administered sulphate of magnesium with only one death.

The Lavage Treatment.—Osler says "that the treatment of dysentery by topical applications is by far the most rational plan," but I think this statement requires qualification. It is unquestionably a valuable method of treatment, but it is only applicable in subacute and chronic cases, at least in the tropics, where the services of skilled nurses are comparatively rarely obtainable. I merely refer to this method for the sake of completeness, as the results of the two previous lines of treatment are so good. For instance, Buchanan has treated 855 consecutive cases by salines, with only nine deaths, giving a case mortality of only 1·05, and these, I think, are almost as good results as can be hoped for in the treatment of an acute illness.

The fourth indication is to counteract any morbid condition of the blood. This is a most important indication, and one which has recently attracted much attention. Where dysentery occurs in a malarial subject quinine must be exhibited in full doses, and Maclean goes so far as to recommend that 20 grains of quinine should always be administered before the ipecacuanha treatment is begun. The morbid condition of the blood which has recently been shown to be frequently associated with dysentery, especially on the Indian frontier, is, however, diminished alkalinity, which Wright has shown to be a frequent cause of scurvy. It must, therefore, be borne in mind that a condition resembling ordinary dysentery may be simply a variety of scurvy, and it may be well, therefore, to test the alkalinity of the blood by the method advised by Wright in all cases of dysentery in which the origin is obscure. Recently in Somaliland a succession of cases of dysentery were found to be due to "acid intoxication," and were relieved by anti-scorbutic treatment.

The fifth and last indication is to maintain the patient's strength. This must be done by suitable diet, as indicated under our second heading, and the administration of stimulants in some cases, but not as a matter of routine. Few will agree with Yeo's suggestion that port and burgundy may be used in acute cases, and the custom of most physicians in the tropics is to prescribe brandy or champagne in the comparatively rare cases in which alcohol is necessary. "Ether and caffeine hypodermically and saline injections have been employed with success in cases in which life appeared to be endangered by hæmorrhage and anæmia with prostration and collapse." Sparteine has also been used with success. After the very acute stage is over, and when the appetite is returning, the strength must be supported by a fairly liberal diet. Egg-and-milk flavoured with nutmeg is an agreeable and nutritious food. Pounded sweetbread, chicken or mutton may be given, with strong soups, and the many varieties of bland farinaceous food of which rice and bread are the types.

The Treatment of Chronic Dysentery.—We now turn to the treatment of chronic dysentery, a condition all too familiar to physicians who have practised in the East. The indications requiring treatment are here merely three in number: (1) to promote a restoration of the diseased mucous membrane; (2) to counteract any morbid tendency in the blood; and (3) to support the patient's strength by proper diet.

(1) Manson's routine in treating all cases of chronic dysentery, a method of which I have had some personal experience, is to give a short preliminary course of ipecacuanha—30, 25, 20, 15, 10, and 5 grains on successive evenings, with rest in bed and milk diet. He then proceeds to give a short course of very small doses of castor oil, with or without opium, three times daily, regulating the dose according to the amount of action produced. If this treatment does good he proceeds to give a mixture of simaruba and cinnamon, with or without some intestinal antiseptic, such as salol or B-naphthol. These measures failing, he has to resort to direct topical applications. Osler and Manson are agreed that these are of the utmost value in the treatment of dysentery, but on one important point the two great authorities differ. The latter insists that topical remedies should never be applied when acute symptoms are present, whereas the former gives the technique for their use in the acute stage of the disease. Nitrate of silver injections are now considered by most authorities to be the best form of local application in chronic dysentery, but solutions of quinine are strongly advocated by Osler in amœbic dysentery, this being with one exception the sole instance in which a remedy peculiar to one type of dysentery is advocated by any of the authors I have consulted.

Recent Bacteriological Investigations.—For the purpose of this paper I obtained the following strains of *B. dysenteriæ*—(1) Shiga's bacillus, I.; (2) Shiga's bacillus, II.; (3) Flexner's bacillus; (4) Vaillard's bacillus; (5) Kruse's bacillus; and (6) *B. dysenteriæ* (non-pathogenic). For the first of these cultures I am indebted to Captain Harvey, assistant professor of pathology, and for the remaining five to Major Fowler, assistant professor of hygiene at the Royal Army Medical College, London. To economise space I have arranged the morphological and cultural characteristics of the various bacilli in the accompanying table, which shows clearly their resemblance to, and difference from, the other members of the coli group of micro-organisms.

Conclusions.—(1) I think that we may take it as bacteriologically proven that notwithstanding slight cultural differences the various strains of bacillus dysenteriæ isolated by Shiga, Flexner, Vaillard, Harris, and Firth are simply varieties of the same organism. Bruce's "G Bacillus" resembles them, but I have not included it in my limited observations, as it was isolated from a single case, and when it arrived in England it was almost dead and had to be revivified by prolonged recultivation. In addition to these pathogenic strains of the organism there are several varieties of so-called pseudo-dysentery bacillus which are non-pathogenic and are to be distinguished from the true bacteria of

TABLE SHOWING THE MORPHOLOGICAL AND CULTURAL CHARACTERISTICS OF BACILLUS DYSENTERIÆ AND THE ALLIED GROUP OF MICRO-ORGANISMS.*

Micro-organism	Character	Motility	Flagella	Growth on nutrient agar	Gelatin stab	Peptone and salt	Neutral red shake	Litmus milk	Sterile potato	Agglutination with dysenteric serum.
Shiga's *B. dysenteriæ* I.	Short rod with rounded ends. No spores. Length 1–3 μ	Motile in recent cultures from stools. Gradually loses motility in sub-cultures.	2–6. Mostly terminal. Rather short and thick.	Semi opaque. Resemble the growth of *B. typhosus*, but are more transparent	Similar to *B. typhosus*, but film which spreads out from puncture usually absent	Faint haziness which rapidly clears. No indol	No appreciable discharge of colour	Becomes feebly acid. After 4 days' incubation acidity has been estimated as equal to 6 per cent. decinormal alkaline solution. No clot	Transparent or whitish growth, which becomes brownish red or dirty grey, with discolouration of potato at edge in a few days	Usually only agglutinates with serum from animal immunised by special strain of *B. dysenteriæ*
Shiga's bacillus II.	ditto	ditto	ditto	Has a characteristic odour called by the Germans "Sperm-geruch"	Growth not seen till 48 hours, and then only slight white growth	ditto	ditto	ditto	ditto	ditto
Vaillard's bacillus	Shorter than Shiga's, otherwise similar	ditto	Numerous fine, reticulated, very long and readily seen (Birt).	ditto	ditto	ditto	ditto	ditto	ditto	ditto
Flexner's bacillus	Similar to Shiga	ditto	Long, thick, and terminal	ditto	ditto	ditto	ditto	ditto	ditto	ditto
Kruse's bacillus	ditto	ditto	Usually 2 terminal	ditto	ditto	ditto	ditto	ditto	ditto	ditto
Pseudo-dysenterial bacillus	Generally somewhat larger than true dysentery bacillus	ditto	Variable	ditto	ditto	ditto	ditto	Slightly acid at first. Afterwards slightly alkaline	ditto	Very variable
B. typhosus abdominalis	Longer than either *B. dysenteriæ* or *B. coli*. "Oval ends" (Muir and Ritchie).	Sub-cultures always very motile.	8–12	More opaque than those of *B. dysenteriæ*	Similar, but surface film usually present.	ditto	ditto	Slight acidity after some days	For several days apparently no growth. Later slight pellicle with velvety surface.	*Nil*
Paratyphoid bacilli	ditto	Not so motile as *B. typhosus* but more so than *B. coli*	Variable	ditto	ditto	ditto	A, usually no change. B, sometimes fluorescence	Paratyphoid A produced acid like *B. typhosus*, and Paratyphoid B produced alkali	Variable	*Nil*
B. coli communis	Shorter and thicker than *B. typhosus*	Motility is not so marked as *B. typhosus*	2–6	More opaque than *B. typhosus*.	Whiter, thicker, more opaque, and showing gas bubbles	Indol production marked	Canary yellow colour produced and gas bubbles	Marked acid and clot	In 48 hours distinct brownish film which rapidly spreads and becomes thicker	*Nil*

* In addition to the culture media and other tests shown in the table the effects of Gram's stain, bile salt broth, mannite nutrose broth, raffinose nutrose medium, salicine nutrose medium, caffeine medium, and agglutination with enteric fever serum were also tried. The effects were as follows. *Gram's stain:* "decolourised" with all nine bacilli. *Bile salt broth:* "acid, no gas" for the first eight bacilli; "acid and gas" for the *B. coli communis*. *Mannite nutrose broth:* "unchanged" for the first five bacilli; "growth and acid" for the pseudo-dysenterial bacillus; "acid" for the last three bacilli. *Raffinose nutrose medium and also salicine nutrose medium:* "acid and growth" for the pseudo-dysenterial bacillus; "unchanged" for the other eight bacilli. *Caffeine medium:* "growth" with the *B. typhosus abdominalis* and the Paratyphoid bacilli; "no growth" with the other seven bacilli. On testing with enteric fever serum the agglutination result was "marked" with the *B. typhosus abdominalis* and "*nil*" with the other eight bacilli.

dysentery by the fact that they act on carbohydrates unaffected by Shiga's and the other pathogenic bacilli and they fail to produce enteritis in animals. Whether, however, these bacilli represent degraded or transitional forms of the true bacillus it is, as yet, impossible to say, (2) That symptoms and intestinal lesions identical with those found in man supervene after the subcutaneous inoculation of rabbits with the cultures of the various strains of *B. dysenteriæ*. (3) That the dysentery organsism have considerable vitality. They will live on clothing for at least three weeks and are said to maintain their virulence in damp soil for months. When spread on bread crumbs, or similar articles of food, they survive for about a week. (4) They are, however, very readily destroyed by heat or by weak solutions of perchloride of mercury or the higher phenols. (5) The specific agglutination reaction with the serum of persons suffering from acute dysentery can generally be obtained within two weeks following the onset of symptoms, but is often poorly marked. It is, however, of some value, and the blood of all patients suffering from a prolonged attack of diarrhœa should invariably be tested with several strains of the bacillus, and the stools subjected to a microscopical examination, as my chief desire in this paper is to call attention to the fact that the character of the stools alone is not to be considered as the test of the presence or absence of dysentery.

I think the most important lesson to be drawn from my investigation of the literature on this subject, and my very limited bacteriological work with the organisms of dysentery, is that the profession has only begun to realise its ignorance of a very great subject and that the clinical entities, which we have hitherto styled dysentery, are not one disease but a group of maladies of very varying degrees of severity, ranging from the acute dysentery so familiar to those of us who have served in India or South Africa, to the simple infective diarrhœa which occurs in infants and adults. Simple diarrhœa may be, and often is, an abortive form of dysentery, as has been shown by the work of Dopter and Jurgens during the early part of 1905. During an epidemic of dysentery there are always a number of cases which are in reality dysentery, but because no blood appears in the stools are regarded as simple diarrhœa, and it is these cases which constitute a grave source of danger to the community, as they may infect others and give rise to attacks of true dysentery. Jurgens has recently examined the stools of twenty-five cases of simple diarrhœa which occurred during an epidemic of dysentery in a camp at Gruppe. He failed to recover the *B. dysenteriæ*, but the serum of one of the cases agglutinated with a strain of the organism. Dopter examined bacteriologically the stools of eleven cases of diarrhœa occurring during an epidemic of dysentery last spring. Seven of these cases were very mild; the *B. dysenteriæ* was, however, recovered from one of them, but the serum reaction in all of them was negative. The remaining four cases did not yield to ordinary treatment and ran a prolonged course, but only symptoms of diarrhœa were observed and no blood appeared in the stools. In one of these cases the *B. dysenteriæ* was isolated, but in all the serum reaction was positive,

In the light of this recent work I submit that all cases of diarrhœa occurring in the tropics should be treated with the same precautions as if they were manifest cases of dysentery, and in hospital should invariably be isolated and their stools sterilised in some simple form of steriliser, or by means of disinfectants. In the Indian hills all fæcal matter should be received on pine needles, and burnt as suggested by me in a communication to the *Journal of the Royal Army Medical Corps*, entitled "The Goux System and its Application to India" (vol. vi., p. 662). If acute diarrhœa and dysentery were recognised in the service as infectious diseases, promptly isolated, and careful disinfection of clothing, bedding, and stools carried out, I believe we should hear less of epidemics of dysentery both in tropical countries and on active service. The Japanese have shown us a good example in the recent war, as they fully recognised dysentery as a communicable disease with, we are told, the happiest results. In conclusion, I maintain that if we can in future warfare secure for His Majesty's troops a pure, or at least, an innocuous, water-supply, an intelligent conservancy, and the prompt recognition and isolation of suspicious cases of diarrhœa, we can confidently hope for comparative immunity from the fell disease, or rather diseases, which have been the scourge of all armies in the field since the day of Agincourt.

Reviews.

A Japanese Text-Book on Plague. By Dr. Tohiu Ishigami, Superintendent Bacteriological Institute, Osaka, Japan; formerly Assistant Bacteriologist to Professor Kitasato. Revised by Professor Shibasaburo Kitasato, Tokyo, Japan. Translated, enlarged and illustrated with Pathogenic Horticulture by Donald MacDonald, M.B., C.M. (Glasg.), late Consulting Bacteriologist to the S. Australian Government. 152 illustrations. 3 plates. (Adelaide: Vardon and Pritchard, Gresham Street, 1905).

Part I.

This text-book is written by one who has closely studied plague in all its bearings. Dr. Ishigami was a member of the Japanese Commission which visited Hong Kong when plague appeared there in 1894 under the leadership of Professors Kitasato and Aoyama. His training in the clinical and bacteriological features of plague was thorough, and he has given us a text-book which is characterised throughout by judical statements, accurate details and many suggestions of an eminently scientific nature as to the means by which the plague is spread. The prophylaxis of the disease is dealt with in a manner which must commend itself to everyone who has studied plague. One of the most interesting parts of the book is that relating to the plague bacillus itself. The question of involution forms of the bacillus, whereby much confusion has arisen in the matter of diagnosis, is clearly stated by Dr. Ishigami. It so often occurs that bacteriologists hesitate to pronounce the disease to be plague, because they meet only with involution forms, that a careful perusal of the paragraphs dealing

with the matter should prove instructive and convincing. At pages 6 and 7 we find: On the first day Professor Kitasato examined the blood of the heart, spleen, liver, lungs, and swollen lymphatic glands of a corpse dead from plague. He found in them a considerable number of strangely original rod-shaped bacilli. On the same day microscopic examinations of the blood obtained from the finger tips of a critical patient revealed the existence in it of similar bacilli.

Subsequent bacteriological examinations of several patients and corpses demonstrated the presence of the same bacillus in every case. But those existing in the blood were regular in shape and smaller, whilst those in buboes or swollen glands and other organs were irregular in shape, and somewhat larger. Both were found to exhibit bipolar staining, the middle part refusing to retain the dye. The cultures made from both varieties were similar in the shape and appearance of their growth. Therefore, Professor Kitasato was of the opinion that those which existed in the glands and other organs were pleomorphic involution forms, and, following a fundamental principle of pathology, attached greater importance to those existing in the blood. Hence he conducted a series of cultivations and experiments on animals, the results of which were made public as explaining the cause of the disease.

A few days after this discovery of Professor Kitasato's, Dr. Yersin, of France, sent out from the Pasteur Institute, arrived at Hong Kong *viâ* Saigon. Conducting his investigations independently of Professor Kitasato, he studied the bacilli chiefly as met with in the glands and organs, which we had considered to be involution forms.

He reported the results of his investigations to the Pasteur Institute as the cause of the disease. Since then, Professor Aoyama has made a special microscopic study of specimens of organs and glands from the plague corpses which have been brought from Hong Kong. He gave out as the result that the bacillus which exists in the glands, and which is decolourised by Gram's method, is an entirely different species to that which exists in the blood, and which is not decolourised by Gram's method.

Part II.

"Plague Pathogenic Horticulture" is contributed by Dr. MacDonald, to which is added a lecture on Plague and "Two Dozen Anti-Plague Golden Rules." The rules are as follows:—

Remember, plague is more "Death" than disease.
Never visit suspected or plague-stricken houses.
Never alter a well-regulated diet.
Wash the hands frequently.
Avoid excesses in diet and wines.
Cook food well and preserve from insects.
Heat serving plates to a high temperature.
Cooking utensils wash with boiled water or water of undoubted purity.
Rather drink weak tea than suspicious water.
Avoid excess in exercise and bathing.
Never handle dead rats.
Destroy your vermin.
Never neglect a trifling wound, cold, or dyspepsia.
Protect the lower limbs well.
Be vaccinated and re-vaccinated if you can.
Keep good fires in winter.
Avoid wet feet.
Preserve the head with sunshades in summer.
Use if you can the mosquito net.
Never exchange pipes.
Never kiss the plague suspect.
Avoid plague apparel unless fumigated.
Never fear, rather be cool, calm, and collected.
Remember cleanliness is next to godliness.

The text-book is fully illustrated and is a valuable addition to plague literature.

Personal Notes.

Indian Medical Services.

Arrivals Reported in London.—Lieutenant-Colonel J. Smyth, Major V. C. Drake Brockman, Major J. A. Hamilton, Captain J. H. Horton, Captain J. L. Robertson, Captain H. Ainsworth.

Extensions of Leave.—Lieutenant-Colonel R. J. Baker, study leave, from April 23rd to June 23rd, 1906, and October 8th to November 8th, 1906; Major T. W. A. Fullerton, furlough to July 1st, 1907; Major C. E. L. Gilbert, three month's furlough; Captain D. S. Baker, one month's furlough.

Permitted to Return to Duty.—Lieutenant-Colonel W. B. Browning.

Postings.

Captain M. Mackelvie and Captain F. P. Connor, services placed at disposal of Government of Bengal.

Lieutenant-Colonel H. Hendly is appointed Civil Surgeon, Kurnal.

Lieutenant F. J. Baley, I.S.M.D., officiates as Civil Surgeon, Singh Bhum.

Military Assistant Surgeon F. G. Cutler, I.S.M.D., is appointed Assistant to the Civil Surgeon, Jubbulpore and Nupt.

Assistant Surgeon J. Robertson, I.S.M.D., officiates as Civil Surgeon, Yeoltmal.

Captain F. T. Thompson, to the Medical Charge 11th Lancers.

Lieutenant Colonel J. Morwood, to be Civil Surgeon, Sultanpur.

Dr. E. J. Simpson, uncovenanted Medical Service, to be Civil Surgeon, Jalaim.

Assistant Surgeon E. Phillips, I.S.M.D., to officiate as Civil Surgeon, Hoshiarpur.

Lieutenant Colonel A. Coates, resumes charge of the duties of Professor of Midwifery and Forensic Medicine, Medical College, Lahore, and Medical Officer in charge of Government College.

Leave.

Major D. T. Lane, private and study leave 12 m.

LIVERPOOL SCHOOL OF TROPICAL MEDICINE.

Yellow Fever Expedition.

The members of the Yellow Fever Expedition from Liverpool, which commenced research work on yellow fever in Brazil in 1905, still continue their investigations. It is satisfactory to know that the medical members of the expedition who were attacked by yellow fever have quite recovered from their illness. A telegram was recently received in Liverpool to the effect that the expedition had succeeded in proving that the chimpanzee can be infected with yellow fever by means of infected *Stegomyia* mosquito. This discovery is likely to prove important from a scientific and practical point of view.

New Instruments.

THE Lawrence patent portable water steriliser for travellers in the Tropics.

We have seen this apparatus at work, and can commend it as both efficient and portable. The price, some £5, places the four gallon per hour steriliser within the reach of all travellers in tropical countries.

Notes and News.

COMMENTING on the first report of the bacteriologists who have been studying the etiology of plague, the *Times of India* says: "The conclusions which these facts force home with remorseless logic is that even with our increased scientific knowledge we cannot secure absolute results against plague, with ordinary sanitary measures. We can reduce the virulence of the seasonal epidemics by rat and flea destruction; we can prepare particular localities to resist the disease through the warning which is now conveyed by the epidemic amongst rats; we can reduce the media of infection by the use of insecticides wherever dead rats are found; we can protect a section of the population by making their dwellings rat-proof; we can raise the resisting power of the people and increase the facilities for sanitary work by improving the conditions amongst which the poor live. But none of these measures, or all of them combined, no matter how vigorously and ably they may be prosecuted, even promise absolute results in the conditions of life of a great Indian city, unless they are combined with the practice of inoculation. It is as true to-day as it was before the Plague Commission set to work that there are only two certain methods of combating plague—to run away from it or to protect one's self against it."

With this somewhat despondent verdict of our lay contemporary we can, however, by no means agree, as Australian experience has shown that rat destruction, properly carried out, may be trusted as a sufficient measure of protection, and though native prejudices may in certain localities place obstacles in the way of the successful operation of the plan, we believe that these difficulties are by no means insuperable, provided that due tact and consideration be exercised in meeting them.

ONE of the Nobel prizes for 1906 has been divided between Professor C. Golgi, of Pavia, and Professor Ramon y Cajal, of Madrid.

ANKYLOSTOMIASIS has been declared to exist in Virginia, United States of America.

THE University of Sydney has established a diploma in Public Health.

MEDICAL supervision of the Mecca pilgrims is being devised on an elaborate scale.

There has been an outbreak of plague at Djeddah, the disembarkation port for Mecca in the Red Sea, and a strict quarantine and medical inspection is being prepared before the pilgrims are allowed to leave Djeddah for Mecca. Half way to Mecca, and again at Mecca itself, the pilgrims are to be medically inspected. An isolation hospital has been established at Mecca.

YELLOW FEVER IN CUBA.—Owing to the relaxation of hygienic measures in Havana, there is evidence that yellow fever is again increasing in the island of Cuba. Under the directing hand of Dr. Gorgas, yellow fever was extinguished in Cuba, but under the *régime* of the Cubans since they were granted self-government, the island, from a hygienic standpoint, is rapidly falling back into the pestilential state which had existed there until the United States Government assumed control.

DURING 1905 the deaths due to wild animals in India were as follows:—Snakes caused 21,797 deaths; elephants, 48; leopards, 401; tigers, 786; wolves, 153. Cattle were destroyed by wild animals to the number of 92,277. No fewer than 16,915 wild animals were killed.

THE mortality of children born in Calcutta during 1905 amounted to 310 in every 1,000.

RATS AND PLAGUE.—The Medical Officer of Health for the City of Madras believes that the freedom of Madras from plague is due to the fact that there are few brown rats infesting the sewers of the city. Were their numbers greater, the disease would in all probability have spread extensively.

MOSQUITO DESTRUCTION.—The introduction of a little silvery fish, named in the Punjab the "Chilwa," and in the Deccan and South India the "Roopha," into pools infested with mosquito larvæ, has proved an efficient means of destroying mosquito life. This fish—the *Cheela argentea*—is found all over India, and would seem an excellent larvicide. Quicklime thrown in stagnant pools has also been used with good effect in the destruction of these pests.

COUNCIL OF MEDICAL INSTRUCTION FOR TURKEY.—UNDER the title of the "Conseil d'Instruction Médicale," a new medical council has been instituted in Constantinople. The duty of this body is to control the medical and sanitary departments of the Ottoman Empire. Professor Mazhar Bey is the president of the Council.

MOSQUITOES AND MALARIA.—At a special meeting of the Bangalore municipal commissioners to consider what steps should be taken to repress malaria, Captain Standage, I.M.S., Residency Surgeon, addressed them on the subject of the connection of the mosquito with malaria. The work done by the Health Department in using kerosine oil on tank borders and ponds justifies the hope that the problem of decreasing malaria is not beyond the capacity of the municipality. He therefore proposed that a pamphlet which he had drawn up on the scheme be printed in several languages and circulated broadcast. This contains a

popular exposition of the mosquito theory, and there are hopes that the people will take kindly to the destruction of mosquitoes. To popularise the theory an experimental school of instruction is to be opened here on December 1st, and will last for four months. It will be open to six officers and non-commissioned officers each from the Poona and Secunderabad Divisions.—*Pioneer Mail, November 23rd*, 1906.

One might wish, however, that, in place of being left to the initiative and enthusiasm of individual officers, anti-malarial sanitation should be adopted and enforced as a universal sanitary policy by the Government of India. The ravages caused by malaria in the cantonments of the Punjab, however, show that this is far from being the case, and this mail's news from Delhi speaks of the disease as raging there in a fashion it certainly could not do if proper steps were taken to limit the mischief. Surely the experience of Havana and Panama, to say nothing of older successes, should suffice to convince the "Little tin gods on wheels" that anti-malaria sanitation is something more than a "doctor's fad."

Recent and Current Literature.

A tabulated list of recent publications and articles bearing on tropical diseases is given below. To readers interested in any branch of tropical literature mentioned in these lists the Editors of the Journal of Tropical Medicine and Hygiene *will be pleased, when possible, to send, on application, the medical journals in which the articles appear.*

"Australian Medical Gazette," October 20, 1906.

I. Polycythæmia and Chronic Cyanosis without Splenic Enlargement.

Reissman, C., contributes an interesting article on this subject. A girl, aged 18, became gradually cyanosed. The liver increased in size as the cyanosis became more chronic. A more or less acute illness, preceded by attacks of unconsciousness, followed by vomiting, diarrhœa, headaches, giddiness, drowsiness, signs of venous obstruction in the chest and leg, hæmoptysis, an increased number of red cells in the blood, increased excretion of chromogen in the urine, and increased coagulability of the blood. Liver abscess was at first suspected, but search for pus in the liver proved negative. A mediastinal tumour suggested itself, but the subsequent history cancelled this belief; the absence of leucocytosis negatived an inflammatory origin. The patient recovered, and the assumption that the venous obstruction was due to thrombosis seems to be rational, especially in view of the fact that of the recorded cases, *post-mortem* evidence seems to point to thrombosis and thrombotic softening. The explanation given by Osler in cases of the kind is that there is increased viscosity of the blood depending upon numerical increase of the red cells.

This disease is in many respects analogous to myelogenic leukæmia, the bone-marrow in one case affording an excess of white cells, but in polycythæmia the red cells are in excess.

Reissman suggests the X-ray treatment for polycythæmia, basing his opinion upon the benefits derived in myelogenic leukæmia for this agent.

II. Parotitis during Dysentery.

Bollen, P., met with a case of parotitis in a child aged 4½, during an attack of dysentery. The child fell ill on May 13th, 1906, and the dysenteric attack ran a typical course. On May 25th a swelling over the right parotid region was observed, which subsequently increased, but by June 3rd had wholly disappeared. There was not suppuration in the parotid, but pain with earache and difficulty in movement of the jaw. The pus in the stools and the swelling in the parotid subsided simultaneously. Parotitis is occasionally mentioned as occurring in dysentery, but the ailment is usually part of a general pyæmic condition and ends in suppuration.

"Treatment," November, 1906.

The Treatment of Tapeworm.

Jubb, G., advises for tapeworm treatment rest in bed for two days, a dose of castor oil on going to bed, a milk diet for two days, on evening of second day in bed a second dose of castor oil. On the morning of the third day, while fasting, a capsule containing 15 minims of extract of male fern is given every fifteen minutes till six capsules have been taken. One hour after the last capsule, a tablespoonful of castor oil. After the oil has acted the patient to resume ordinary diet. Jubb finds that male fern exhibited as recommended is equally efficient for *Tænia mediocanellata* or for *T. solium*. The head is best sought for by causing the stool to be dropped in water and searched for in a shallow porcelain tray.

"Medical Record," August 4, 1906.

Splenic Extract in the Treatment of Malaria.

Carpenter recommends the fresh extract of spleen in 5 grain doses every four hours. In quartan and æstivo-autumnal types a hæmatinic is usually required in addition, but in the acute tertian and quotidian types the splenic extract alone is sufficient.

"Semaine Medicale," September 26, 1906.

Zanardini, G., advocates the use of creasote enemata in dysentery, made as follows: 1 drachm of a 10 per cent. solution of creasote is added to the yolk of one egg and made into an emulsion with a litre of water.

Billet has also used creasote in the form of one-quarter to one-half litre of an emulsion made by a 1 or 2 per cent. solution of creasote in almond oil. These enemata are administered twice daily for as long as symptoms continue.

"La Clinique," May 18, 1906.

The Treatment of Leprosy.

Unna considers chaulmoogra oil is the nearest approach to a specific remedy for leprosy we possess. The drug can be given by the mouth or by the rectum, but should not be administered hypodermically, owing to the pain it causes. In order to overcome the difficulties of local medication from thickening of the tissues and the obstruction of the lymphatics by the lepra bacillus, Unna recommends the application of local heat and massage. The parts may be covered with flannel and ironed, or baths of "ink" at a temperature of 86° F., combined with massage. The applications serve to dislodge the bacilli and render them more liable to destruction by ointments containing ichthyol, chrysarobin, pyrogallol, or other bactericides. The ink bath consists of a solution of sulphate of iron and tannin.

Notices to Correspondents.

1.—Manuscripts sent in cannot be returned.

2.—As our contributors are for the most part resident abroad, proofs will not be submitted to those dwelling outside the United Kingdom, unless specially desired and arranged for.

3.—To ensure accuracy in printing it is specially requested that all communications should be written clearly.

4.—Authors desiring reprints of their communications to the Journal of Tropical Medicine and Hygiene should communicate with the Publishers.

5.—Correspondents should look for replies under the heading "Answers to Correspondents."

Colonial Medical Reports.—No. 17.—BASUTOLAND.

Medical Report for the Year ending December 31st, 1904.

By EDWARD CHARLES LONG, M.R.C.S., L.R.C.P.

Principal Medical Officer.

Population.

The census taken in 1904 shows a remarkable increase in the population. In thirteen years, the native population has increased 60 per cent. The number of Europeans, which of course bears an insignificant proportion to the total population, now amounts to 895, as against 578 in 1898.

Of the natives 163,216 are males and 184,515 females. The only age test applied in the census was an under and over fifteen years age limit: 174,043 were under 15 years, and 173,688 over 15 years of age.

There is a good deal of local overcrowding, an evil which, I think, is increasing and unnecessary, seeing that the population works out at 34 per square mile. The natives are housed in huts which are usually placed very close together, forming small villages. The huts are, as a rule, unventilated and very little air circulates between the huts. The ground around them is fouled with all sorts of refuse, excreta, &c. These customs undoubtedly have an unfavourable influence on the health of the community, and coupled with the more general use of European clothing, are partly responsible for the marked increase in tubercular disease, to which subsequent reference will be made.

As there is no registration of births and deaths, no trustworthy information is available concerning the birth and death-rate. The mortality amongst young children is high, and speaking from general impressions, I should say that the death-rate amongst young people generally, is higher than it used to be.

General Health.

The year 1904 was an exceptionally healthy one. The number of patients treated at the dispensaries was less than the previous year, and there were no epidemics.

Small-pox.

No cases of small-pox were recorded during the year. This highly satisfactory state of affairs is undoubtedly due to the energy with which vaccination has been prosecuted during recent years. The majority of the inhabitants have now been vaccinated, and a fair proportion re-vaccinated.

24,301 vaccinations, all with calf lymph, were performed during the year. The value of vaccination is now thoroughly appreciated by the natives. Instead of opposition, we now have frequent applications from chiefs and headmen for vaccinators to be sent to their districts.

Enteric Fever.

Sporadic cases of typhoid have been recorded. The majority of the cases admitted into hospital were labourers who had contracted the disease in neighbouring territories.

Tuberculosis.

I regret to have to record a noticeable increase of tubercular diseases throughout the territory. The increase is traceable to (1) tuberculosis contracted during residence at mining centres; (2) overcrowding in the villages, and insanitary surroundings and habits; (3) the general adoption of European clothing; (4) to direct infection.

A noticeable proportion of the men who have been engaged in underground work at the mines return suffering from miners' phthisis. This cause cannot, of course, be dealt with here. With a view to combating the other causes and instructing the natives in the elementary principles of sanitation and public health, a small pamphlet on the subject has been written, translated into Sesuto, for distribution throughout the native schools. If the reading of this little book is made compulsory in the schools, much good may be looked for by the people thus receiving some simple instruction during youth in those most important subjects, public health and sanitation.

The figures given in the nosological return do not, I think, represent the real number of tubercular cases in the country. Many cases returned as adenitis would, I feel sure, be found to be tubercular, if they could be followed up. Two cases of acute miliary tuberculosis came under my notice during the year, the diagnosis being confirmed by *post-mortem* examination.

Syphilis.

This disease is still an important factor in relation to the health of the nation. The returns show no diminution in the number of cases treated. The widespread prevalence of the disease is having an appreciable effect in lowering the physique of the people.

The identity of syphilis and so-called yaws has been fully discussed in a previous report. As some observers still regard yaws as a separate disease, I would again point out that the experience of medical officers in this country proves that every lesion delineated in Fasciculus XIV. of the New Sydenham Society's Atlas finds its counterpart in syphilitic natives in Basutoland.

New Growths.

Benign growths are still frequently met with, and specimens of all growths are forwarded to the Cancer Research Fund. Malignant growths are extremely rare.

Goitre.

This disease is never seen in the Basuto, but Fingos are very subject to it. It is fairly amenable to treatment by painting with iodine, and the internal administration of iodine of potassium and arsenic.

One case which ended fatally is worth recording. A female Fingo, aged 20 years, was admitted with a large bilateral goitre. It diminished slightly in size under treatment, but the patient, who was a fine healthy-looking young woman, was anxious to have it removed by operation. While waiting for operation, and being apparently in excellent health, the temperature suddenly rose one day to 106° F., accompanied by a very rapid pulse, muscular tremors, and cold sweats. In spite of all treatment, the symptoms persisted, and the patient died forty-eight hours after the first onset of the unfavourable symptoms. No *post-mortem* examination was obtainable.

Rheumatism.

This disease seems to be more prevalent in dry years. The subacute and chronic forms are the most common. Many acute cases probably escape observation from inability to attend at the dispensary. A considerable proportion of the more chronic cases would appear to be gonorrhœal in origin.

We find large doses of perchloride of iron, with saline purgatives, the most efficacious treatment.

Diseases of the Circulatory System.

The increasing number of heart cases is traceable to the prevalence of rheumatism. Syphilis, as far as my observation goes, does not seem to affect the vascular system in natives. Most of the patients only seek advice when the disease is far advanced. Mitral stenosis and incompetence are the most common forms of valvular disease. One death occurred from pericarditis, in which the pericardium was universally adherent.

Respiratory System.

Catarrhal pharyngitis and bronchial catarrh were prevalent during the winter months. Pneumonia was less prevalent than during the previous year.

Generative System.

The only cases calling for notice under this heading were one of hypertrophied prostate in a very old native; the prostate was enucleated by the suprapubic operation, and weighed 8¼ oz. The other case was one of extrauterine fœtation, which was successfully treated by laparotomy.

Diseases of the Nose.

A case of empyema of the frontal sinus, with necrosis of the anterior wall of the sinus, was treated by trephining the sinus, curetting and drainage.

Diseases of the Eye.

The method of subconjunctival injections has been given a fair trial during the year, but the expectations of its value have not been realised.

Meteorology.

This does not call for special notice. The year was again unusually dry, the rainfall being about 12 inches below the average. The crops were, however, saved, and a sufficient food supply assured to the inhabitants. The winter was long and exceptionally cold, but does not appear to have had any ill-effect on the general health.

Colonial Medical Reports.—No. 18.—Northern Nigeria.

MEDICAL REPORT FOR THE YEAR 1903.

By Dr. S. W. THOMPSTONE.

Principal Medical Officer.

ESTIMATED POPULATION FOR THE YEAR 1903.

THE average European population resident in Northern Nigeria during the year was 309. This includes both officials (civil and military) and non-officials (traders, missionaries, &c.).

DEATHS.

There were 18 deaths during the year, 12 amongst officials, and 6 amongst non-officials. Of the total deaths 3 occurred in action, and 1 from ptomaine poison, leaving altogether 14 deaths which were attributable to the effects of the climate.

DEATH-RATE PER 1,000.

This gives a total death-rate of 58·25 per 1,000 calculated on the average resident population, or, excluding the four deaths above referred to, of 45·3 per 1,000.

COMPARISON WITH LAST YEAR.

Last year the average resident population was 290, and the number of deaths 9, a death-rate of 31·03 per 1,000. There has been an increase of population over last year therefore of 19, and in the total death-rate of 27·2 per 1,000. Comparisons made between statistics

of mortality based on such a relatively small population as that of Northern Nigeria, which has been occupied by Europeans for so short a time, are, however, obviously fallacious, and until records of a number of years are available it cannot be stated that the death-rate of one year is above or below the normal rate.

PREVALENCE OF SICKNESS IN THE DIFFERENT SEASONS OF THE YEAR, AND CHARACTER AS TO MILDNESS OR SEVERITY OF DISEASES PREVAILING.

The months of September, October, November and December, show the greatest amount of sickness, and March, April, May and June, the least, the rainy season having been the most unhealthy part of the year.

The character of the various diseases met with has not changed, with the exception that blackwater fever has assumed a more severe form, the cases have been more serious and the death-rate higher.

RELATIVE MORTALITY IN THE DIFFERENT SEASONS.

The greatest number of deaths in any one month occurred in September. There were no deaths in February, June and August.

METEOROLOGICAL CONDITIONS OF THE SEASONS.

The rainfall during the year was 32·88 inches at Zungeru, and 59·85 at Lokoja—the greatest recorded having been at Lokoja in September, when it amounted to 13·97 inches in the month. The average at the two stations at which complete records were kept was 46·36 inches for the year. The maximum shade temperature in Lokoja was 101° in March, the minimum 56° in January. The highest mean temperature was 84·4° in March, and the lowest 78·4° in August. Last year the maximum shade temperature was 102° in June, and the minimum 51° in December. The highest mean temperature was 85° in April, and the lowest 72° in November. The rainfall at Lokoja in 1902 was 53·61 inches. In Zungeru the maximum shade temperature was 107°, which was recorded in March, and the minimum 60° in November. The highest mean temperature was 89·7° in March, and the lowest 78·4° in August. The highest mean relative humidity was 86·6 per cent. in August, and the lowest in December, 55·4 per cent. Hygrometrical observations were not taken, however, until May. The general direction of the wind was S.W. for the greater part of the year both at Zungeru and Lokoja. I append a chart which shows graphically the seasonal variations of mean temperature, relative humidity, rainfall and sickness rate.

New meteorological stations have now been established in all provinces, and returns will be available for the next annual report, which will give more representative records of the different degrees of temperature, rainfall, and relative humidity met with throughout the Protectorate.

PARTICULAR DISEASES DURING THE YEAR.

The prevalent diseases among Europeans have been malarial fevers and dysentery. Of the former (excluding blackwater) there were 384 admissions with 2 deaths, and of the latter 41 admissions with no deaths. Sixteen cases of blackwater fever occurred throughout the Protectorate during the year, with 6 deaths, a case mortality of 37·5 per cent. There were 3 cases of small-pox amongst Europeans, with no deaths.

GENERAL SANITARY CONDITION OF THE PROTECTORATE.

The general sanitary condition of the stations occupied by Europeans is being improved gradually, but much yet remains to be done. The Government premises are kept clean, and are well drained, but the water supply in most out-stations is poor, and the houses merely temporary mud and grass structures. The native towns, with the exception of those in the vicinity of the European settlements, are practically in their primitive condition.

ZUNGERU.

Sanitary State of the Principal Stations with reference to Water Supply, Drainage, &c.

Average European population, 50.

Deaths during the year, 5.

The general sanitary condition of Zungeru is good, the cantonment is kept clean, and is well supplied with surface drains running down to the Dago river, which effectually carry off all surface water. The general health of Europeans throughout the year has been good.

Water Supply.

The water supply is derived from the Dago river, which flows through the cantonment; it has not proved satisfactory during the dry season, owing to the extreme drought, drinking water having had to be carried a long distance from the Kaduna river. A scheme is now in progress for damming the stream, which is hoped will keep it running in future. Tanks are also being fitted round the bungalows to collect rain-water. A pumping station on the Kaduna would solve the problem of obtaining a good supply the year round.

Disposal of Refuse.

The dry earth system for the disposal of excreta is in use, and has proved satisfactory—the contents of pails being buried in trenches. All combustible refuse is burnt, and the rest buried at some distance from the cantonment.

LOKOJA.

Average European population, 42.

Deaths during year, 2.

The sanitation of Lokoja has much improved recently—the Government premises being in good condition, and the lines occupied by native soldiers clean.

Water Supply.

This is derived from the Niger river, and is distilled before being issued for drinking purposes; the supply is ample, and the quality all that can be desired.

Disposal of Refuse.

As at Zungeru and all other Government stations.

Drainage is satisfactory, by surface drains to the river.

The hospital accommodation is quite inadequate for a station of this size, through which all the invalids in the Protectorate pass on their way to England. A new hospital is, however, now in course of erection, which will amply meet all requirements for some years to come. It will probably be ready for occupation In April next.

ILLORIN.

European population, 12.
Deaths during the year, 1.
The sanitary condition of this station is good, except as regards the position of the native barracks, which are too near the Europeans. These are being moved.

Water Supply.

The drinking water for the Europeans is obtained from a well about 30 feet in depth; its quality is fair.

Disposal of Refuse.

As in all other stations.
Drainage good.

SOKOTO.

European population, 8.
Deaths during the year, none.
The general sanitary condition is good. There is, however, a good deal of swamp in the wet season near both the fort and the Residency, which requires draining. Much has been done, but much still remains. Near the fort it is especially improved, but that near the Residency is a much more serious matter, and will take much time and labour to render satisfactory from a sanitary point of view. All that can be done is being done in this direction.

Water Supply.

This is obtained from rock springs in good positions; the water is of excellent quality.

Disposal of Refuse.

As elsewhere.
Drainage: Open drains have been, and are being cut, to take off surface water.

KANO.

European population, 14.
Deaths during year, none.
The European station is situated about three-quarters of a mile from the native town of Kano, and consists of the Residency and the military lines, the latter lying about 200 yards south-east of the former. The Residency used to be the former Emir's summer residence, and consists of blocks of houses and several outhouses. The general sanitary condition is satisfactory, except during the rains, when drainage is difficult, owing to the flatness of the surrounding country.

Water Supply.

All water is obtained from wells, and is boiled and filtered before use.

Disposal of Refuse.

By burning and in trenches.

ZARIA.

European population, 25.
Deaths during the year, 1.
The present site occupied by the civil population is unsatisfactory. The military lines have been moved four miles away to Dandua, a much better position from a sanitary point of view; the question of moving the civil population is under consideration.

Water Supply.

This is poor, being derived from wells, none of which are above suspicion, the quality is inferior, and the supply meagre.
At Dandua there is a running stream of good water.

Disposal of Refuse.

As in other stations.

YOLA.

European population, 8.
Deaths during the year, none.
The sanitary condition of this station is good. In the early part of the year much annoyance was caused by mosquitoes. A "mosquito brigade" was organised in August, and the Medical Officer reports that he has now filled all possible breeding places within 800 yards of the Residency with sand and planted grass over them. Mosquitoes are now rarely found in the vicinity of the European dwellings.

Water Supply.

The water is obtained from the Benue, poured into settling jars, boiled, and passed through a Berkefeld drip filter.

Drainage.

Good, except in one place, to the west of the Residency, where a swamp formed during the wet season. This, however, only existed for a short time when the rains were at their heaviest.

VACCINATIONS PERFORMED DURING THE YEAR AND THE CONDITION OF THE POPULATION IN RESPECT OF PROTECTION FROM SMALL-POX.

Systematic vaccination in Northern Nigeria has been commenced during the year. Arrangements have been made for a small weekly supply of lymph to be sent to all stations, as it is found from experience that there is great difficulty in obtaining it in an active condition if kept in this climate for more than a few weeks at the outside.

The native population is at present (with the exception of 174 cases successfully vaccinated during the last three months, and those who have already suffered from the disease) entirely unprotected from small-pox. On account of the enormous size of the Protectorate, and the relatively small staff available for these duties, it will be many years before much can be done to vaccinate even a small proportion of the inhabitants, but in view of the frequency of outbreaks of this disease, it is of the utmost importance that active measures should be taken to protect, at any rate, those natives who live in the vicinity of European stations.

Colonial Medical Reports.—No. 18.—Northern Nigeria— (*continued*).

GENERAL HEALTH.

Europeans.

The general health has not been so good as last year, both the death and invaliding rates having been higher for all classes of the community. Analysis of the statistics of mortality for the year shows that the death-rate from climatic causes among Government officials has been remarkably less than among the non-official population. There were resident during the year an average of 273·8 officials in the Protectorate, amongst whom there were 9 deaths from disease, a death-rate of 3·2 per cent., the average resident non-official population for the same period being 35·2 with 6 deaths, a death-rate of 17·04 per cent.; the non-official death-rate being 13·8 per cent. greater than the official for the year.

There have been 34 officials and 9 non-officials invalided in the twelve months, a total invaliding rate of 13·9 per cent.

Natives.

The total number of natives treated at the Government hospitals and dispensaries during the year was 3,983, an increase over the previous year of 876. A serious outbreak of small-pox occurred at Lokoja in June. The disease was introduced by freed slaves brought down the Benue. Fortunately, however, by prompt isolation and vaccination of contacts it was prevented from spreading to the native town. There were altogether 77 cases, with 8 deaths.

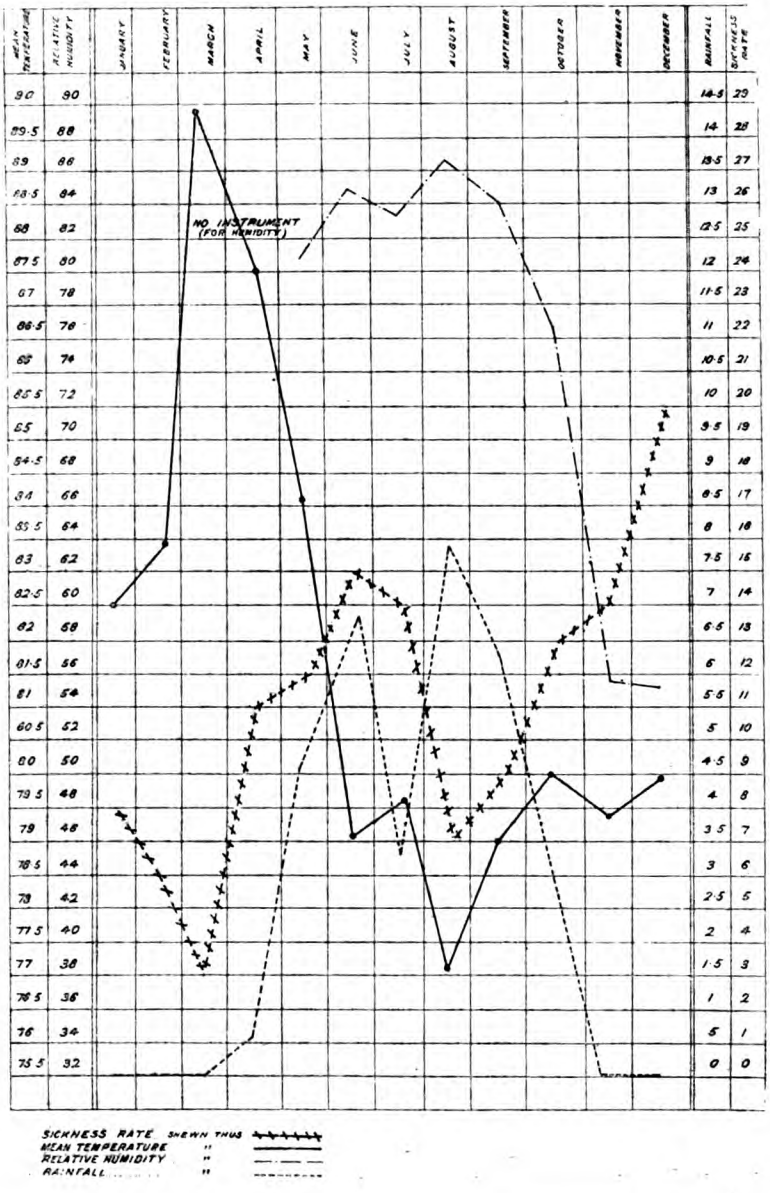
Steps are being taken for the provision of permanent enclosures for the isolation of infectious disease both at Lokoja and Zungeru, in which grass huts, which can be burnt when no longer required, will be built as wanted.

The amount of venereal disease met with is still regrettably large, there having been 627 cases of gonorrhœa treated during the year, and 98 cases of syphilis.

I attach the following returns:—

A. Statistics of European population.

B. Nosological Returns, Zungeru.[1]



No. 19.—Northern Nigeria.—Medical Report for 1904.

By DR. S. W. THOMPSTONE, *Principal Medical Officer.*

ESTIMATED POPULATION FOR THE YEAR 1904.

As in former years statistics of European population only are given, it being impossible to estimate with any approach to accuracy the number of natives in the Protectorate.

The average number of Europeans resident in Northern Nigeria during the year was 322, including both officials and non-officials—312 being males and 10 females.

DEATHS.

There were 13 deaths in all during the year, 8 amongst officials, and 5 among non-officials. Of these deaths 1 was due to accident, leaving 12 attributable to climatic causes.

DEATH-RATE PER THOUSAND.

The total death-rate for the year, calculated on the average resident population, and including deaths from all causes, was 40·37 per 1,000, or excluding the one accidental death, 37·26. There is a very noticeable difference in the relative mortality of officials and non-officials, there having been 5 deaths

[1] Diagram only printed.

amongst 52 non-officials, as against 8 deaths (including one from accident) amongst 270 officials, giving a non-official death-rate of 96·15 per 1,000, and an official one of 29·62. This difference being brought about almost entirely by the more careful selection of candidates for employment in Government service, and by their shorter tour of residence—many of the men sent out by the trading firms being obviously physically unfit for tropical service.

Comparison with Previous Year.

Last year the average resident population was 309, and the number of deaths 18—the death-rate being 58·25 per 1,000. There has been an increase of European population over last year of 13, and a decrease in the death-rate from all causes of 17·88 per 1,000.

Prevalence of Sickness in the Different Seasons of the Year, and General Character as to the Mildness or Severity of the Diseases Prevailing.

As in former years, the rainy season was the most unhealthy for Europeans, July being the worst month, and the month with the heaviest rainfall. The smallest number of admissions was recorded in February. The general character of the diseases prevailing showed no change except in the case of hæmoglobinuric fever, which has become more prevalent but has assumed a milder type. There were 31 admissions with 5 deaths from this disease during the year—a case mortality of 16·1 per cent.—as against 16 cases with 6 deaths in 1903. An increase in the number of cases with a very marked reduction in the death-rate—the case mortality last year having been 37·5 per cent.; one case of enteric fever occurred in Bornu—the first recorded in Northern Nigeria.

Relative Mortality in the Different Seasons.

There was practically no difference in the relative mortality in the different seasons, the deaths being pretty evenly distributed throughout the year. There were no deaths during the months of January, March, September, and December.

Meteorological Conditions of the Seasons and their Probable Effect with Regard to Health.

Zungeru.—The rainfall during the year was 51·1 inches, or 18·22 inches more than in 1903, the wettest month being July, with 15·07 inches. Rain fell during eight months of the year, from March to October, inclusive—the heaviest fall recorded being 2·64 inches in the twenty-four hours, on August 24th. The maximum shade temperature was 103° F. in March and April, the minimum, 56° F., which was recorded in November, December, and January. The highest mean temperature was 86° in April, and the lowest 77° in July, August, and December, the mean temperature for the year being 79°. The mean relative humidity for the year was 63·6 per cent., the highest mean being 82 for July, and the lowest 38 for December—calculated from readings taken at 9 a.m. The lowest actual relative humidity recorded was 15, from hygrometer readings taken at 4 p.m. on December 27th.

Lokoja.—The total rainfall was 41·72 inches for the year, or 18·13 inches less than last year—the heaviest rainfall having been in July, 8·34 inches. The maximum shade temperature was 102° on March 11th, and the minimum 57° on December 23rd. The highest mean temperature was 86° in March, and the lowest 79° in July, August, September, and December. The mean temperature for the year was 80° F.

Yola.—Total rainfall 33·77, the greatest recorded being 10·99 inches in August; the heaviest fall occurring on June 21st, 2·10 inches.

The mean temperature for the year was 80°, the maximum being 107° F., which was recorded on March 16th, and the minimum 60°, on January 13th.

Complete statistics are not available from any other stations, as their meteorologlcal instruments did not arrive until after the commencement of the year.

The general direction of the wind throughout the Protectorate was from the south-west from June to November, and from the north-east during the remaining months of the year; the Harmattan lasting, with slight intermissions, from December to the end of May; the first tornadoes occurring in March, and the rainy season ending in October.

With regard to the probable effect of the meteorological conditions on the health of the community, it may be stated generally that Europeans have the best health in the dry season, and natives in the rains. Europeans, by taking proper precautions, avoiding in great part the diseases that affect the native in the dry season when water is scarce and polluted, and the native being less affected by the great cause of the excessive mortality among Europeans—malaria—a disease more especially of the wet season.

Particular Diseases that have Occurred during the Year.

By far the greatest amount of sickness during the year has been due, as in the past, to malaria; the total admissions from this disease (excluding blackwater fever for the sake of convenience) having been 515, with 3 deaths, compared with 386 admissions with 2 deaths last year. Thirty-one cases of hæmoglobinuric fever occurred with 5 deaths, and 18 of dysentery with no deaths. Dysentery is becoming much less prevalent, the total admissions for the year being less than half those in 1903. There were two cases of small-pox among Europeans, with no deaths.

General Sanitary Condition of the Protectorate.

The general sanitary condition of the European stations is good. The principle of forming separate locations for natives and Europeans has been carried out in all cases as far as possible, and sites have been chosen for permanent buildings in the headquarters of the various provinces. The question of improving the water supply is being solved in great measure by the supply of small condensers.

The large native towns are still in their original condition as regards sanitation, and it will be probably many years before anything can be done to improve them. They are kept clean as far as outward appearances go, but the old system of digging wells and privies side by side obtains everywhere, and probably accounts for most of the intestinal diseases met with amongst natives.

Sanitary State of the Principal Stations with Reference to Water Supply, Drainage, &c.

Zungeru.—The headquarters of the Protectorate has an average resident population of 69·5 Europeans, 66 officials, and 3·5 non-officials. The cantonment is kept clean, and is well supplied with surface drains running down to the Dago river, which effectually carry off all rain-water. Early in the year a series of dams was constructed across the river with the object of holding up the water and providing for a continuous flow throughout the dry season. The system has proved most successful, and a condenser has been erected which provides the European residents with a plentiful and pure supply of drinking water the whole year round. In addition to this, iron tanks have been fitted to most of the bungalows to store rain-water during the wet season.

Disposal of Refuse.—The dry-earth system is in use for excreta—as is the case in all Government stations—the contents of the pails being emptied into shallow trenches and buried. All combustible refuse is burnt daily, and the rest buried at some distance from the cantonment.

The general health of the official population has been good; that of the employés of the Niger Company extremely bad. This difference is due, as pointed out earlier in this report, principally to the want of care exercised in the selection of suitable men, and the long tour of service required of them.

Lokoja had an average resident population during the year of 65·9 Europeans, 51·7 officials, and 14·2 non-officials. The sanitary condition of the European quarter is good, and the lines occupied by the native soldiers are well kept and clean. The cantonment is well supplied with surface drains running down to the Niger, and refuse is disposed of as at all other stations.

Drinking water is supplied by a condenser from the river; the supply is ample, and the quality excellent. The new hospital for Europeans, referred to in my last report, has been completed, and has been in use since May. It is cool, well ventilated, and large enough to meet all requirements for some years to come.

Zaria.—The average resident European population during the year was 23. The site now occupied by the civil population is most unsatisfactory, the water supply is insufficient and bad, and the ground unsuitable. A new site at Dandua, five miles away, has been occupied by the military during the year, and has proved to be an excellent one. It is proposed to move the entire European population out there early in 1905, and abandon the old situation at Zaria.

The health throughout the year has been good, there having been no deaths. The water supply at Dandua is obtained from a running stream, and is of good quality and ample in amount.

Kano.—The average resident European population during the year was 18·4; the general health was fair.

The sanitary condition of the site at present occupied is as good as the nature of the ground will allow. Drainage is unsatisfactory during the wet season owing to the flatness of the surrounding country—no proper fall being obtainable, and the soil becoming waterlogged in heavy rains. The water supply is obtained from shallow wells, and is insufficient for the needs of a large population during the dry season. The question of moving to a more suitable locality is under consideration, and several alternative sites have been proposed; no particular place has, however, yet been decided on, the local conditions varying so much at different seasons of the year, that it was considered inadvisable to make a final choice until more extended observations have been made.

Vaccinations Performed during the Year, and Condition of the Population in Respect of Protection from Small-pox.

One thousand three hundred and four successful vaccinations have been performed during the year, all stations being now supplied with a small weekly or fortnightly consignment of lymph. Great difficulty is experienced in obtaining it in an active condition at those stations which are farthest away in the interior, the long journey on carriers' heads in the hot weather rendering it in many cases inert on its arrival. The returns received from the different stations show a regularly decreasing scale of successful vaccinations, according to the distance from Lokoja; Lokoja itself heading the list, with Katagum and Bornu at the bottom.

There have been two more cases of small-pox among the white population during the year, again demonstrating the fact that the disease can be acquired from natives, and refuting the popular theory held by many Europeans to the contrary. The natives throughout the Protectorate, with the exception of those successfully vaccinated during the last two years and those who have already suffered from the disease, are entirely unprotected from small-pox, and all that can be done at present is to vaccinate all Government employés and those natives living in the immediate vicinity of the various stations, anything like general vaccination, though most desirable, being quite impracticable.

General Health during the Year.

The general health of the European community has been fair; the death-rate has been considerably lower, but the sickness and invaliding rates higher than last year. More cases of illness have come under treatment, but of a milder type. There have been 50 officials and 17 non-officials invalided during the year, a total invaliding rate of 20·8 per cent., as compared with 13·9 per cent. last year.

The health of the natives has been good through the year, no serious epidemics have occurred, and the death-rate, so far as can be gathered, has been normal. The total number of natives treated at the Government hospitals and dispensaries was 13,504, an increase over the previous year of 9,521. This very large increase is, however, partly accounted for by a change which has been made in the method of keeping the records of cases—no account having been kept in the past of many of the patients. Dispensaries are being established in the native towns nearest the different provincial headquarters, but they will necessarily be only on a very limited scale at first, the expense of equipping fifteen or twenty stations with the necessary

instruments, drugs, and appliances being very great.

During the year 883 patients have been treated as paupers throughout the Protectorate.

With the object of providing for the isolation of infectious diseases, such as small-pox, &c., in Zungeru and Lokoja, permanent enclosures have now been built in each of these stations, one acre in extent, surrounded by unclimbable iron fencing, and provided with lock-up gates. It is intended when the necessity arises to build temporary grass huts within them, which can be put up quickly when wanted and burnt when no longer required.

Venereal diseases have been very prevalent among natives, syphilis being widely distributed throughout the northern and eastern parts of the Protectorate. Nine cases of beri-beri, eight of them at Lokoja, have been admitted during the year, with two deaths. This disease is not endemic so far as can be ascertained, and all cases met with have occurred in the parts of the Protectorate nearest the sea, and in direct communication with the coast.

I attach the following returns :—

* Hepatic Abscess.

Colonial Medical Reports.—No. 20.—The Gold Coast.

MEDICAL AND SANITARY REPORT

FOR THE YEAR ENDING DECEMBER, 1904.

By Dr. KENNETH F. T. BUÉE.

Acting Principal Medical Officer.

(1) General Remarks.

The general health of the Colony has been good.

There has been some increase in the number of cases of small-pox, but the number of deaths has been much lower, 1 in 62, as against 11 in 37 last year.

Measles cases were more numerous, 16 against 6, but there were no deaths.

Dysentery was more prevalent, and shows a total of 82 with 23 deaths, against 56 with 10.

Malaria was slightly less than last year, while the European population is nearly one-tenth greater.

The rainfall throughout was, on the whole, less, an increase over last year being only noted at Axim and Kwitta, and last year's average was low; the result was that in many places lack of water was seriously felt, and vegetables were scarce.

(2) Health of the European Community.

How Employed	Number	Deaths	Invalided	Death-rate per 1,000	Invaliding-rate per 1,000
Officials..	351	8	27	22·79	76·92
Mercantile Firms, &c.	305	3	22	9·83	72·13
Mining Companies	1,222	13	97	10·63	79·37
Missions	75	1	11	13·33	146·66
Total	1,953	25	157	12·80	80·38

The return gives at a glance the points of the European health.

As compared with last year there were more Europeans; the deaths were fewer and the invaliding-rate slightly higher. It seems as though the steps taken everywhere to keep down mosquitoes are bearing some fruit, but in this direction we have been distinctly helped by the dry season.

(3) Native Population.

The health of the native population is fair, the dry weather has in many cases been a cause of suffering and ill-health.

The principal diseases treated were malarial fever, diseases of skin, ulcers, yaws, diseases of intestines and respiratory organs.

Small-pox was not prevalent; there is almost always some present, and probably will be till the whole of the population has been vaccinated; for the most part the people do not raise conscientious objections and it is mainly due to the moving part of the population that small-pox is kept alive, since they are not easily vaccinated.

(4) Meteorological Report.

A new station will be started at Sekondi in January. The reports from Accra, Aburi, Cape Coast, Axim, Kwitta, Kumasi, and Gambaga are appended.

The most noticeable feature is the low rainfall, less even than last year.

(5) Gaols of the Colony.

Reports were received from Accra, Adda, Akuse, Axim, Cape Coast, Elmina, Kumasi, Kwitta, Saltpond, Sekondi, Tarkwa, and Winneba.

The general health was good. The number of cases treated in hospital was 332, and of these 18 died.

The deaths were as follows:—

Sekondi	3
Elmina	2
Cape Coast	3
Saltpond	2
Accra	4
Adda	1
Akuse	1
Kumasi	2
Total	18

The general sanitary condition of the different prisons was as good as could be expected, taking into consideration the class of building in use. Most of prisons are old forts, and in many cases are badly

adapted for the requirements of a gaol. There are very few solitary cells, and the prisoners are confined in associated wards; a custom to be condemned on physical, sanitary, and moral grounds. A central prison for long-sentence prisoners is on the Estimates for this year. The water and food are generally good and sufficient.

The medical officers in charge of the various gaols report as follows;—

Accra.—General health very good throughout the year. Diet good; water good, but occasionally rather scarce. Ventilation of cells good. The prisoners are employed at trades in the prison, and outside at road making and repairing, street repairing, sanitary work, &c.

Adda.—Health good; diet and drinking water good; ventilation poor. Prisoners employed repairing public roads and general scavenging.

Akuse.—On the whole the health of the prisoners during the year was good. Diet and water good; ventilation of cells and wards good.

Axim.—The general health of the prisoners during the year was good. Food good; water good; ventilation of cells and wards fair. Prisoners employed at road repairing, whitewashing, carrying water, &c.

Cape Coast.—Health good; both diet and drinking-water good. Some difficulty in obtaining a sufficient supply of good water during the dry season; ventilation of cells and wards primitive and inadequate; the accommodation is insufficient. Prisoners employed at emptying latrines, cutting firewood, clearing Government land, and carrying water.

Elmina.—Health good; diet and water good; ventilation of cells and wards quite inadequate—very bad. Prisoners employed at cooking, grinding corn, mat and basket making, and public works.

Kumasi.—Health good; food and water both sufficient and good; ventilation fair. Prisoners employed at road-making and cleaning, garden, and general scavenging.

Kwitta.—On the whole the health has been good; diet good; water fairly good; cells and wards are not well ventilated. Prisoners employed for emptying latrines, labour on town roads.

Saltpond.—General health has been good; diet and drinking water good; ventilation satisfactory; employed at usual work.

Sekondi.—General health good; diet and drinking ing water good; ventilation of cells and wards not very good. Prisoners employed at road making and sanitary work.

Tarkwa.—General health fairly good; diet and drinking water good; ventilation of cells and wards not very good. Prisoners employed at usual general work.

Winneba.—General health fairly good; diet and drinking water good; ventilation of cells and wards good. Prisoners employed at usual general work.

(6) The Lunatic Asylum.

There were 71 patients remaining under treatment in the asylum at the end of 1903, and during the year 1904, 34 new cases were admitted, making a total of 105 cases, 83 males and 22 females. During the year 30 were discharged from the asylum, 14 died, and 1 absconded, leaving 60 patients under treatment at the end of 1904. Of the patients who died 12 were males and 2 females; an inquest was held in every case. The health of the lunatics has been fairly satisfactory, and of the 14 deaths during 1904, 12 were in-patients who had been recently brought in from Axim and Sekondi districts.

The food of the inmates of the asylum has been generally of good quality. The water supply is good and the quality excellent; it is stored in the large tank situated in front of the asylum, and its distribution has been carefully supervised.

The occupation of inmates consists chiefly in gardening, emptying latrines and general household duties. A few patients take willingly to work in the garden; most, however, refuse absolutely to do any work.

(7) Sanitary Report.

During the past year great improvements in the sanitation of many of the principal towns in the Colony have been carried out, more especially in the Cape Coast and Sekondi. The resistance to sanitation on the part of the native population of Cape Coast still continues, but not to such an extent as during the previous year, although it is still comparatively active. In other towns it is of a more passive nature; the native is satisfied with the conditions in which he has lived for centuries, and does not wish for anything better.

I append a short summary of the sanitary condition of the principal towns:—

Accra.—The control of the sanitation of Accra is vested in the Town Council. This body, in July, 1903, obtained the services of a European Inspector of Nuisances, trusting that the employment of such an official would tend to promote greater cleanliness and a general improvement in the sanitation of the municipal area. As regards the general cleanliness of the main streets and dust-bins of the town, there has been some improvement, but much yet remains to be done to improve the back streets and outskirts of the town. The water supply, the disposal of sewage, and the removal of ruinous buildings, are all most important, and are all receiving attention. The present dust-bins are inadequate in size, and are being replaced, as funds permit, by larger and better ones. A properly erected incinerator would be of great benefit to the town. An Order in Council has been issued that all tanks, wells, &c., should be rendered mosquito-proof. The new market has been opened at Christiansborg.

Cape Coast.—Great difficulty is experienced in dealing with the drains in many parts of the town. This is largely due to the peculiar construction of these drains and to their being inaccessible. The difficulty is chiefly felt in dry weather.

Owing to the latrines having to be emptied by prison labour, this work has not at all times been satisfactorily performed. The Medical Officer of Health has no authority over these men.

This will probably be improved now that a European gaoler has arrived.

The water supply for domestic purposes is unreliable both as regards quantity and quality.

The work of cleaning the town, filling up holes,

treatment of refuse, and general prevention of Anopheles breeding, continues.

Sekondi.—The neighbourhood of Sekondi is more or less hilly, and certainly picturesque. European Sekondi is well segregated from Native Sekondi, and is proportionately healthy and clean in consequence. Many of the official bungalows are built on the surrounding eminences facing the sea, and a delightful breeze does much to mitigate the unpleasantness of the high temperature.

The town naturally lends itself to sanitation, and its newness, segregation, and cleanliness are factors that will tell considerably as regards its suitabliity for European habitation. There is no reason why Sekondi should not be one of the healthiest towns on the West Coast.

The small rainfall and the consequent scarcity of drinking water, and the presence of the lagoon between Accra and Lagos Towns are perhaps the two greatest drawbacks to contend with, but these are not insurmountable difficulties nor should they be very costly ones.

Axim.—The town of Axim is in a fairly good sanitary state. The number of scavengers is limited, considering the area of the town, but they are assisted by prison labour. The outlying villages are not in a satisfactory state, as most of the inhabitants are engaged in the catching and curing of fish.

Elmina.—The town of Elmina has been kept clean, and as free as could possibly be done from mosquitoes, by supervision being strict in not allowing stagnant water to remain in empty tins, &c. This, no doubt, accounts for the comparative freedom from malarial fever.

The other towns in the district when visited have on the whole been found fairly clean.

Tarkwa.—The sanitary condition of Tarkwa is good. Water is plentiful and fairly good.

Kwitta.—The station is at present in fairly good order. The streets are fairly clean, the town is dry and healthy. The Government bungalows are in good order.

In nearly all the other towns of the Colony some sanitary improvements have been carried out; but there is nothing of any special interest to record.

(8) Departmental.

Medical Officers.—The Medical staff has been up to its full strength.

One medical officer died during the year.

European Nursing Staff.—The staff has been up to its full strength.

Dispensers.—The staff of dispensers is at present below its strength, owing to resignations and dismissals.

Native Nursing Staff.—This is also at present short-handed.

Appendix I.

REPORTS ON HOSPITALS.

Report on the Colonial Hospital, Accra, for the Year ended December 31, 1904.

I have the honour to report that I took over charge of the above hospital from Dr. Rutherford on December 10th, 1904, Dr. Kennen being in charge of the Dispensary.

There have been no important structural alterations during the year. The large tank in front of the asylum has been repaired and cleaned.

In-patients.

The number treated during the year 1904 was 383, as against 469 in 1903.

The 383 for 1904 were compared as follows :—

Europeans 23, as against 51 for 1903.
Native officials 28, as against 45 for 1903.
Civil Police 127, as against 118 for 1903.
Native non-officials 201, as against 255 for 1903.
Hausa W.A.F.F., 4.
Small-pox in 1904, 9.

Out-patients.

New cases, 1904 :—

Males 969, as against 1,759 for 1903.
Females 629, as against 1,170 for 1903.
Civil Police 987, as against 1,164 for 1903.
Old cases treated during 1904, 3,079.

Twenty operations were performed during the year, with two deaths.

The mortality amongst Europeans remains low, there being but one death in hospital (non-official); the same as in 1903, and against three in 1902, and seven in 1901.

The native mortality in hospital was 33, as against 31 in 1903.

Expenditure.

The total expenditure for diets in 1904 was £172 9s. 10d., as against £265 8s. 2d. for 1903. The largest expenditure was in the month of February, £20 10s. 10d.; the lowest in May, £9 2s. 6d. The amount recovered from patients was £87 14s. 3d., as against £145 5s. 7d. for 1903.

An examination was held in July for druggists' licences; there were three candidates, of whom one passed.

Dispensary.

The dispensary has been under the charge of Mr. Cato, assisted by Mr. Laryea.

Nursing.

During the year the nursing has been under the charge of Nursing Sisters Oram, Marshall and Fraser, and a native staff.

The Hospital.

This is well kept, considering the deficient water supply, *vide* Meteorological Report *infra*.

Native nurses and dressers are difficult to obtain; considering night work and the care and attention their employment necessitates, their salaries are inadequate for suitable persons.

Meteorological.

Readings have been taken twice daily.

Rainfall 17·28 ins., as against 20.04 in 1903.

The largest rainfall was in May, 3·90 ins., and June, 8·97 ins.

The highest solar radiation reading was in May, 145·83.

Shade minimum, 62·87, in July.

(Signed) R. D'Arcy Irvine,
Senior Medical Officer.

Colonial Medical Reports.—No. 20.—The Gold Coast— (*continued*).

Report on the Colonial Hospital, Axim, for the Year ended December 31, 1904.

The hospital consists of a European ward of three beds, and a native ward of eight beds. A store-room, pharmacy, and two bedrooms, one of which is occupied by the dispenser and the other by the dresser.

Both wards are large enough for ordinary requirements, but both have been fully occupied on two occasions.

The hospital has been painted during the year, and is now in a much more satisfactory state.

The number of new patients treated in the out-patient department was 802, as compared with 740 in 1903. The attendances of old cases were 2,555, as compared with 4,023 in 1903.

The number of patients admitted into hospital was 162, as compared with 50 in 1903. Very many of these cases, however, did not contract their illness in Axim, but were sent in from outlying bush villages, mining companies, and timber concessions on the Ancobra River. There were several cases admitted, practically moribund, the total number of deaths for the year being thirteen.

(Signed) A. MACQUEEN,
Medical Officer.

Report on the Colonial Hospital, Cape Coast, for the Year ended December 31, 1904.

The number of admissions for the year was considerably lower than that of the preceding year, being 306, against 586 in 1903. This is largely accounted for by the marked improvement in health of both European and Native communities. It is also probable that the floating population in Cape Coast has decreased very considerably since 1903. There was also a marked decrease in small-pox, 100 more cases being recorded in 1903 than in 1904.

Thirty deaths were recorded for the year—a number that cannot be regarded as large when we consider that in many cases natives only bring a case to hospital when they have given up any hope of treating it successfully themselves.

(1) Remittent malarial fever.

(2) Pulmonary diseases, such as bronchitis, pneumonia, pleurisy.

(3) Intestinal diseases, such as dysentery, diarrhœa, colic.

(4) Small-pox, and a number of injuries of various nature.

Amongst those cases admitted there were three diagnosed as cerebral hæmorrhage, having aphasia without loss of consciousness in the early stage.

One case of sleeping sickness occurred in a Hausa soldier. In deference to Mahomedan custom a *post-mortem* examination was withheld.

A convict prisoner admitted with brain symptoms of an indefinite character, accompanied by fever, died after some days' illness.

As I suspected cerebro-spinal meningitis, I held a *post-mortem* examination with Dr. Claridge. Well-marked meningitis was discovered, and pus was found between the brain and the arachnoid membrane.

Amongst the injuries, one case of severe extensive burn ended in death from shock.

One case of gunshot wound died.

A case of compound fracture of the femur led to amputation of the thigh, the case being now nearly fit for discharge from hospital.

In the case of the European who died in hospital, it would appear that his sickness commenced as an infectious influenza cold, as the two Europeans in the factory contracted the disease at the same time. The deceased had been under treatment of a private practitioner, who left the country soon after, and I was called to see the case.

I found the patient was in a state of delirium, due to the abuse of alcohol, and he had been wandering about the house in the night, although in a most serious condition, his temperature being at 106°.

He was admitted to the hospital without delay. I found well-marked symptoms of pneumonia present. The delirium continued until collapse and unconsciousness set in, the patient dying within twenty-four hours. I am convinced that early systematic treatment in hospital would have saved the life in this case.

The other death was that of Dr. W. A. Murray, Deputy Principal Medical Officer, the cause being blackwater fever. Two points are worthy of notice in connection with this case. First, that it was the second attack of this little understood and treacherous climatic disease.

The first attack occurred about the middle of 1894, more than ten years ago.

The second point worthy of notice is that Dr. Murray had just returned from a trying journey through Ashanti, and I understand he was not very fit in health on arrival in Cape Coast.

The case was not entered as an admission to hospital, as Dr. Murray died in his quarters adjoining the hospital. The remaining European cases admitted to hospital presented an unusually mild type of malarial fever, chiefly remittent, and formed a marked contrast to the severe cases common here some years ago.

EQUIPMENT.

The equipment was fairly satisfactory.

STAFF.

The staff was adequate and efficient for the greater part of the year. The European nurse was taken away from this station in October. There was little work for a nurse during the year.

DISPENSARY.

A total of 2,508 cases were attended at the dispensary, mostly of a trivial nature. The prevalent diseases were :—

(1) Pulmonary diseases, such as bronchial catarrh.

(2) Intestinal complaints, such as dysentery, diarrhœa and constipation.

(3) Rheumatism.

(4) Affections of the eye.

(5) Affections of the ear.

(6) Injuries.

(Signed) P. J. GARLAND,
D.P.M.O.

Report on the Colonial Hospital, Sekondi, for the Year ended December 31, 1904.

During the year the medical duties have been carried out by Dr. Buée and myself, I acting until March 11th, and Dr. Buée from the latter date until September 14th, when I again relieved him, and have continued to act until the present time.

During the year the sanitary duties have been carried on by Drs. Beringer, Le Fanu, and Collier in succession.

EUROPEAN HOSPITAL.

The European hospital consists of two wards. The smaller is used for higher grade officials, and contains four beds. The larger is used for second grade officials, and contains eight beds.

Both wards are well ventilated and comfortable in every respect. The whole hospital is kept clean and in good order, and is in a good state of repair.

NATIVE HOSPITAL.

The Native Hospital is situated at some distance from the European, and is well ventilated, clean, and in good repair.

The hospital is made up of three wards, which are as follows:—

One large ward	10 beds
Small ward A	2 ,,
Small ward B	2 ,,
Total	14 ,,

Wards "A" and "B" are set apart for native officials, the large ward being allotted to non-official patients.

There are store-rooms, dispensary, operation room, bath-rooms and other usual offices attached to the hospital.

The supply of instruments and drugs is fairly good.

There have been a fair number of minor operations, and several major operations, including amputation, &c., which I am glad to say have been generally successful in result.

The number of patients treated in hospital was as follows:—

In-patients ...	Europeans ...	191	
	Natives (males)...	121	
	,, (females)	2	
	Civil Police ...	12	
	Total ...	326	
Out-patients	Europeans ...	0	New cases.
	Natives (males)...	1,261	
	,, (females)	81	
	Civil Police ...	132	
	Total ...	1,474	
Out-patients	Europeans ...	0	Old cases.
	Natives (males)...	2,029	
	,, (females)	110	
	Civil Police ...	201	
	Total ...	2,340	

There were thirteen European officials invalided, and two deaths; one from blackwater fever and one from cerebral hæmorrhage.

Amongst the non-officials (European) there were five deaths, only one of these being a permanent resident in Sekondi, the others came in sick from outlying districts. There were no deaths among the native officials.

Amongst the non-officials (natives) the deaths were as follows:—

Males	16
Females	1
Civil Police	*nil*
Total	17

The number of deaths, including all classes, both Europeans and natives, being summarised as follows:—

Europeans	Officials	2
	Non-officials	5
Natives	Non-officials (males)...	16
	Females	1
	Total	24

The majority of cases of illness occurring among the Europeans have been malarial fever of the various types.

REVENUE.

Amount recovered from officials, in-patients (European and native) ...	£228	16	6
In-patients (Civil Police)	2	3	6
,, (Civil non-officials) ...	110	13	0
Amount paid by dispensary paying patients	3	10	0
	£345	3	0

EXPENDITURE.

Expenditure for diets, provisions, fuel, &c., £362 7s. 11d.

The medical staff at present is as follows:—
Medical Officer—W. S. Webb.
Medical Officer of Health—J. H. Collier.
Nursing Sister—A. Wallace.
,, ,, M. Marshall.
Dispenser—F. W. C. Wulff.
Dressers—Four.

The native staff is fairly good. I have always found Mr. Wulff a trustworthy and accurate dispenser.

(Signed) W. S. WEBB,
Medical Officer.

Report on the Colonial Hospital, Adda, for the Year ended December 31, 1904.

I have the honour to forward a Report on the Colonial Hospital at this station, for the year 1904.

I took over the duties of Medical Officer from Dr. Lunn, my predecessor, on February 6th, 1904, since which date I have acted in that capacity.

The buildings consist of a hospital with three wards, a male, a female, and one for Europeans. The

number of beds available for natives are ten, and one for Europeans. There are also two latrine rooms, a dispenser's room, store- and bath-room recesses. The building is completed by one consulting room and dispenser's two living rooms. There are two out-buildings, one being a building composed of a kitchen and three rooms. The hospital is bright, airy, and comfortable, while this, as well as the outbuildings and surroundings, have been kept regularly clean.

ATTENDANCES.

New cases (including 157 paying patients) 1,151, and old cases 1,615. There is a great decrease in the numbers of both new and old cases, and this is the result of the fact that the majority of patients who could afford to pay refused treatment when they are asked to do so.

Fees collected, paying patients during the year, £4 13s. 10d.; average fees charged, 6d. first time, and 1d. each attendance afterwards.

IN-PATIENTS.

There have been forty-two admissions during the year; eight deaths occurred. Two were brought into the hospital in a moribund state, and one died in one hour after admission of fracture of the pelvis, and one, a consumptive, twenty-four hours after admission. The other six died from (1) rupture of the bladder, (2) gunshot wounds, (1) pneumonia, (1) malignant new growth of leg, (1) injury to spine.

There were no major operations, but there were several cases of minor types.

There has been no small-pox, no vaccination performed. One case of diphtheria occurred during the last quarter, out-patient (a child 2 years old) died two days after admission.

(Signed) G. CHARLES WALKER,
Medical Officer.

Report on the Colonial Hospital, Kwitta, for the Year ended December 31, 1904.

BUILDINGS.

The hospital building is a good one. The infectious diseases building is set apart from the hospital, about 100 yards distant. Has not been used this year.

DRUGS, &C.

Drugs and dressings have been sufficient.

IN-PATIENTS.

Sixty-one were treated in the hospital, with five deaths. *Filaria medinensis* caused most admissions.

OUT-PATIENTS.

925 received medicine at the dispensary, mostly paupers. A number came from the outlying villages. Intestinal complaints, skin diseases and injuries were most common. Cases of true tropical diseases are not prominent.

SMALL-POX.

There has been no small-pox, and no vaccination.

(Signed) F. S. HARPER,
Medical Officer.

Report on the Colonial Hospital, Elmina, for the Year ended December 31, 1904.

I have the honour to submit to you the annual report for the medical work carried on at Elmina for the year ending December 31st, 1904.

BUILDINGS.

No alterations have taken place in the buildings during the past year.

The building, &c., is sufficient for the demands made upon it.

WATER SUPPLY.

The supply of water in the tank in the hospital yard is of sufficient quantity to last out the dry season. The quality is good.

DIET, &C.

The diet of the patients has been good both in quality and quantity, the latter being quite liberal.

DRUGS.

The drugs have always been of sufficient quantity to meet all demands.

PATIENTS.

Very few patients have been treated in hospital, and none of those of a dangerous condition, with the exception of a double pneumonia and strangulated hernia.

OPERATIONS.

Since taking over there have been no serious operations, with the exception of one strangulated hernia mentioned in the preceding paragraph.

LATRINES.

The latrines provided are in every way sufficient.

INCOME AND EXPENDITURE.

The income was £7 17s. 9d., and the expenditure was £45 9s. 3d.

(Signed) W. B. THAIN,
Medical Officer.

Report on the Colonial Hospital, Saltpond, for the Year ended December 31, 1904.

During the past year the general health of the Europeans, officials and non-officials has been good. The principal diseases have been malarial fevers and dysentery.

No deaths have occurred, but two non-officials have been invalided, one from remittent fever, by my predecessor in the early part of the year, and the other from blackwater fever, this last December.

During the year there have been 981 new cases and 2,555 subsequent attendances.

Fees to the amount of £8 9s. 6d. have been collected.

Thorough weekly inspections of the town have been made by me since my arrival in July, and the town has been maintained in a good sanitary state.

The scavenging and latrine arrangements have been well carried out under the efficient supervision of the Inspector of Nuisances.

Several water-holes and pools where mosquitoes have been found breeding have been filled up. Many ruined houses have been pulled down, and vacant ground has been fenced in and so kept cleaner.

There has been no small-pox during the year.

The work of the dispensary staff has been entirely satisfactory. I have found Mr. Sutton, the dispenser, invariably most efficient, very willing, and courteous to the patients. Mr. Quansah, the dresser, has also proved most useful, painstaking and trustworthy.

(Signed) ARTHUR E. HORN,
Medical Officer.

APPENDIX II.

Medical Report on Ashanti for the Year 1904.

The health of Kumasi has shown a great improvement during the year 1904, both in the number of officials placed on the sick list and the severity of the attacks of fever.

111 officials were placed on the sick list during the year, and out of that number four were invalided—three to England and one to the Canaries; this latter officer returned and completed his tour. One case of blackwater occurred, and no death took place.

These figures compare very favourably with 1903.

I append comparative list.

INVALIDING.

Four officials were invalided, one to Canary, three to England; both the latter were permanently invalided.

MEDICAL OFFICERS.

Two medical officers have been stationed in Kumasi, and all out-stations have each had the services of one during the year.

SUBORDINATE STAFF.

I am glad to be able to report that Kumasi has had a second dispenser stationed.

MEDICAL STORES.

Good and sufficient for present requirement.

INSTRUMENTS.

Kumasi is fairly well supplied with instruments.

HORSES,

I am glad to say, have shown an improvement, although the death-rate amongst them is still high.

WATER.

European supply good.

Native supply is abundant and good.

QUARTERS FOR EUROPEANS.

Good.

LATRINES.

Pan System.—I understand that 500 pans are on order; this will be of great service to Kumasi in enabling it to be kept in a good sanitary condition.

During the year six latrine houses have been erected in different parts of the town, and are much appreciated by the community.

METEOROLOGICAL CONDITION.

The most remarkable features in the meteorological condition during the year were the heavy rains falling in the months of June and December, as compared with 1903, and the postponing of the Harmattan wind until late in December.

Owing to the short time since merchants have started living here it is difficult to judge as to their health, but so far it has been good.

HEALTH OF NATIVE OFFICIALS

has been good throughout the year. A decided falling off has been shown in the admissions to and attendance at hospital of members of the West African Frontier Force.

OUT-STATIONS.

General Health.—The health of the out-stations in Ashanti has been good throughout the year, with the exception of Odumassi in the north-west of Ashanti; the health at this station has been decidedly bad, two fatal cases of blackwater occurring; and one official was unable to complete his tour of service owing to chronic malaria. The health of the other officials has not been satisfactory.

KUMASI.

Average Official Population	No. placed on Sick List	No. of Cases Blackwater Fever	Number

* Invalided to Canary, returned to Colony and completed tour.

† Out of this number 13 suffered from ptomaine poisoning due to bad tinned food.

‡ Invalided to the Islands; died at Canary.

(Signed) H. TWEEDY,
Senior Medical Officer.

APPENDIX III.

Medical Report, Northern Territories, for the Year 1904.

NORTHERN TERRITORIES.

The Northern Territories are divided for administrative purposes into four districts, the White Volta District, the Black Volta District, the Gonja District, and the Kintampo District, and at the headquarters of each district a medical department is maintained. During the early part of this year the headquarters of the Gonja District was removed from the town of Salaga to that of Yegi.

Colonial Medical Reports.—No. 20.—The Gold Coast—(*continued*).

Yegi lies close to the River Volta, about one day's journey from Salaga.

In the six months for which statistics are available the health of all ranks at Yegi has been very inferior to that at Salaga, but too short a period has elapsed since the change to warrant any generalisation from the facts collected.

The following table shows the total number of all ranks who served in the Northern Territories in 1904:—

European Officials	Native Officials	Gold Coast Regiment	Station Carriers
46	29	573	375

Health—Europeans.

All important variations in the health of the European officials are shown in Table A.

They suffered from the following diseases:—

Diarrhœa	2 cases.
Gastritis	1 ,,
Hæmoglobinuric fever	2 ,,
Intermittent malarial fever ...	17 ,,
Remittent malarial fever ...	40 ,,
Renal colic	1 ,,
Vomiting (at Wa) (symptom only)	1 ,,

Thus of a total of 64 cases of illness 59 were of malarial origin.

Invaliding.

Two European officials were invalided during the year after recovery from hæmoglobinuric fever.

Deaths.

No deaths of Europeans were recorded. A military officer who left Gambaga, having completed over a year's service, died of hæmoglobinuric fever shortly after landing in England.

The Age Average of Officers.

Officers under 30 years appear to suffer more severely from disease than those above that age. Unfortunately the age average is decreasing. At the beginning of the year, at Gambaga, it was between 30 and 40 years, but in the latter part of the year it fell to between 20 and 30 years.

A similar decrease is, I believe, common to other stations.

The Native Official.

Health.—All important variations in health are shown in Table B.

They suffered from the following diseases:—

Continued fever	5 cases.
Abscess	2 ,,
Bronchitis	1 ,,
Abscess of liver	1 ,,
Constipation	1 ,,
Diarrhœa	1 ,,
Tonsillitis	1 ,,
Injury	1 ,,

Of 29 native officials serving, 11 were admitted to the sick list during the year.

Invalided: There was no invaliding.

Death: There was no death.

The native official is really a stranger in the Northern Territories, where his mode of life is not that of the Coast town he comes from.

His food also differs greatly from that he is accustomed to at home, on account of the complete absence of plantain, or Koko Yam, from the Northern Territories dietary.

It will be observed, notwithstanding, that he enjoys excellent health, and that his ailments are usually of trifling importance.

Gold Coast Regiment.

All important variations in the health of the Gold Coast Regiment, 2nd Battalion, are shown in Table C.

The men suffered chiefly from the diseases arranged below, in the order of frequency:—

Guinea-worm, continued fever, injuries, constipation, bronchitis, gonorrhœa, syphilis, rheumatism.

Invaliding: Eight men were invalided as unfit for military service, suffering from syphilis, gonorrhœa, cardiac disease, necrosis of bone.

Deaths: Seven deaths occurred during the year from the causes stated below:—

Pneumonia	4 cases.
Epistaxis	1 ,,
Pyæmia	1 ,,
Intestinal obstruction ...	1 ,,

Station Carriers.

All important variations in the health of the station carriers are shown in Table D.

They suffered chiefly from the following diseases arranged below in the order of frequency:—

Constipation, guinea-worm, injuries, bronchitis, rheumatism, diarrhœa, remittent fever, gonorrhœa, syphilis.

Invalided: Twenty men were invalided as unfit for work from syphilis, phagedæna, hernia.

Deaths: Two deaths took place, one from cirrhosis of the liver and one from pneumonia.

Townsfolk.

A total of 1,247 persons were treated at the five dispensaries during 1904.

These persons represented all grades of native society from the towns and villages near the dispensaries. They suffered chiefly from the following diseases, arranged in order of frequency:—

Ulcers, injuries, bronchitis, constipation, ringworm, conjunctivitis, syphilis, guinea-worm, yaws, rheumatism, gonorrhœa.

Sanitation.

The control of the sanitary arrangements is in the hands of the Medical Officer.

There is one Inspector of Nuisances at Gambaga.

Latrines.

Pan latrines are supplied for the use of European officials, and the pans are emptied twice a day by prison labour. Pit latrines are supplied for the use of

the native population. The latrines are dug and kept in good order by prison labour.

Rubbish heaps are formed at suitable places chosen by the Medical Officer, and the heaps are burned weekly.

Slaughter Houses.

All animals to be slaughtered for use as food are daily examined by the medical officer, who has the power to veto the slaughter of those he may consider unfit.

Infectious Disease.

No epidemic of grave infectious nature has occurred during the year.

A mild epidemic of chicken-pox occurred at Wa.

An epidemic of mumps has prevailed at Gambaga for the past three months.

No cases of small-pox were recorded.

The Medical Department.

The medical establishment in the Northern Territories consisted of :—

1 Senior Medical Officer.
4 Medical Officers.
1 Dispenser.
4 Dressers.

Hospitals.

Gambaga.—There is an excellent hospital of ten beds, with operation room, consulting room, dispensary, store, mortuary, kitchen and quarters for the dispenser and dresser.

There is an isolation hospital for infectious diseases. 299 cases were treated in 1904.

Kintampo.—There is a hospital of three beds, with dispensary, store and quarters for the dresser.

Forty-five cases were treated in 1904.

Salaga.—There is a hospital of eight beds, with dispensary and store.

353 case were treated in 1904.

Yegi.—The erection of a hospital will be begun next year. A dispensary and store have been already built.

Three cases treated (in the store) in 1904.

Wa.—There is a hospital, with dispensary, store, kitchen and dresser's quarters.

Ninety-one cases treated in 1904.

Meteorology.

The meteorological station for the Northern Territories is situated at Gambago.

It is supplied with the following instruments :—

Solar maximum thermometer.
Shade maximum ,,
Shade minimum ,,
Dry bulb ,,
Wet bulb ,,
Rain guage.

From Table E it will be seen :—

(1) That the rainfall amounted to 40·51 inches.

(2) That the rainfall occurred in seven months, from April to October inclusive.

(3) That there were five rainless months.

(4) That the average humidity varied almost directly as the rainfall.

(5) That the average minimum temperature approximately corresponded to the average dew point during the rains only.

(6) That during the rainless months there was no dew.

The rainfall for the last three years was :—

1902	...	...	...	31·59 inches.
1903	...	...	...	43·03 ,,
1904	...	...	...	40·51 ,,

TABLE E.

MONTHLY AVERAGES OF DAILY METEOROLOGICAL OBSERVATIONS AT GAMBAGA, NORTHERN TERRITORIES, 1904.

1904	Average Solar Maximum	Average Shade Maximum	Average Shade Minimum	Average Dewpoint	Average Relative Humidity	Average Extreme Daily Range	The Total Rainfall	Remarks
January	143·35	92·32	69·74	50·23	34·54	22·90	0·00	(1) The season of the rains is preceded and closed by thunderstorms accompanied by violent gales of wind.
February	147·03	92·75	70·41	48·65	30·48	22·34	0·00	
March	154·09	95·41	75·67	58·30	32·70	19·74	0·61	
April	151·50	93·76	73·48	59·08	46·66	18·33	1·74	(2) Hail fell once in May and once in June.
May	146·00	85·38	72·82	64·26	57·80	12·51	6·65	
June	153·23	84·73	69·86	66·66	71·00	14·86	3·19	(3) Early in December the wind changed to N.E., and the so-called Harmattan season began.
July	139·96	79·03	69·90	70·24	83·67	9·19	10·01	
August	144·00	79·61	71·38	70·36	82·77	8·22	7·25	
September	153·26	80·50	70·20	70·80	79·26	10·30	7·97	(4) During the season a strong breeze usually prevails day and night.
October..	150·29	83·00	71·29	71·88	77·64	11·70	3·09	
November	148·50	90·00	71·66	€8·63	56·26	18·33	0·00	(5) The total annual rainfall was 40·51 inches.
December	143·80	90·38	69·35	57·60	41·00	21·03	0·00

Colonial Medical Reports.—No. 21.—The Straits Settlements.

MEDICAL REPORT FOR THE YEAR 1904.

By Dr. D. K. McDOWELL, C.M.G.

Principal Civil Medical Officer, Straits Settlements.

POPULATION AND HEALTH.

(1) The following table shows the estimated population and the birth and death-rates for the years 1903 and 1904 for the several Settlements.

(2) The death-rate for the whole of the Colony was 39 in 1904 as against 39·49 in 1903 and 42·96 in 1902, and judging from this there seems to have been an improvement in the public health of the Colony in 1904 over the two previous years.

Settlement	Estimated mean Population		Births		Deaths		Birth Ratio per Mille.		Death Ratio per Mille.	
	1903	1904	1903	1904	1903	1904	1903	1904	1903	1904
Singapore	240,833	246,495	5,089	5,435	11,505	10,937	21·13	22·05	47·77	44·37
Penang	130,121	130,602	2,495	2,493	4,988	5,517	19·17	19·08	38·33	42·24
Dindings	4,236	4,294	136	158	137	128	32·10	36·79	32·34	29·80
Province Wellesley	117,078	117,762	3,813	3,778	3,279	3,392	32·57	32·08	28·01	28·80
Malacca	96,276	96,629	3,976	3,380	3,332	3,259	41·30	34·97	34·61	33·73
Total	588,544	595,782	15,509	15,244	23,241	23,233	26·35	25·59	39·49	39·

From this table it will be seen that there was a considerable reduction in the number of births in Malacca in 1904 as compared with 1903. Singapore, however, shows an increase in the birth-rate and an appreciable reduction in the death-rate, a result which was also obtained in 1903 as compared with 1902.

(3) Of the total number of deaths registered in 1904, 3,841 were among infants of under one year old, against 3,865 in 1903, and 3,631 in 1902. Of the total deaths registered in Singapore in 1904, 284 were among persons who had resided less than one month in the Settlement.

(5) *Beri-beri.*—Two thousand six hundred and thirty-one cases were admitted into hospital with 879 deaths in 1904, as against 1,919 cases with 647 deaths in 1903, and 1,901 cases with 575 deaths in 1902. The total number of deaths registered in 1904, 1903 and 1902 respectively, were 2,287, 1,729, and 1,607. It will be seen, therefore, that this disease has a tendency to increase. Five cases of beri-beri occurred in the General Hospital and 60 in the Tan Tock Seng's Hospital among patients admitted for other diseases. There were 266 cases of beri-beri in the Singapore Prison as against 169 in 1903, but the percentage of deaths was lower in 1904. Following the good result of former years 30 prisoners with beri-beri were transferred to Malacca from Singapore, but the result was not satisfactory.

	Plague				Cholera				Small-pox			
	1903		1904		1903		1904		1903		1904	
	Cases	Deaths	Cases	Deaths	Cases	Deaths	Cases	Deaths	Cases	Deaths	Cases	Deaths
Singapore	3	3	20	20	226	190	3	3	109	29	33	11
Penang	..	..	..	..	..	..	..	..	227	57	3	2
Province Wellesley..	..	..	..	..	..	..	..	..	258	49	6	2
Malacca	..	..	..	..	..	..	..	..	266	40	100	7
Total	3	3	20	20	226	190	3	3	860	175	142	22

(4) The above table gives the number of cases of zymotic diseases in the several Settlements in the years 1903 and 1904, and deaths therefrom, not including cases imported into the Colony.

Plague.—The 20 cases in Singapore in 1904 all proved fatal. They occurred in different parts of the town among 17 Chinese and 3 Tamils. Two of the cases were said to be among late arrivals in Singapore, but this could not be definitely ascertained.

Cholera.—Only 3 cases, all fatal, were reported in Singapore, one occurring in the prison. There were none in the other Settlements.

Small-pox.—One hundred and forty-two cases with 22 deaths were reported in all the Settlements, being a great decrease over the figures for 1903.

Enteric Fever.—This, I am afraid, is on the increase. One hundred and seventy-nine cases with 69 deaths were reported in Singapore, as against 148 cases and 47 deaths in the year previous. One hundred and seventy-three cases were treated in hospitals in the several Settlements. Of these 75 died. Three cases occurred in the Singapore Prison.

Diphtheria.—Seventeen cases were reported in Singapore with 9 deaths.

(6) *Venereal Diseases.*—The admissions to all the hospitals for 1904 numbered 1,784, with 95 deaths. In 1903 there were 1,818 admissions, with 96 deaths, and in 1902, 2,341 admissions, with 90 deaths. Of those admitted in 1904, 237 were females, of whom 152 were prostitutes.

(7) Owing to the overcrowding and bad sanitation phthisis is very much on the increase, 1,644 deaths have been registered in Singapore alone, or 2,534 for the Colony.

(8) *Sanitation.*—With the continued overcrowding in Singapore the sanitation cannot be said to be in a satisfactory state. There is practically no sewerage system. The drainage in many places is bad, and the water supply is being constantly cut off. The time has come, I think, when the question of remedying these defects should be seriously considered by the authorities concerned. The want of a good and plentiful water supply is undoubtedly one of the chief causes of the high mortality rate. In

	Number of Patients Treated			Number of Deaths.			Percentage of Deaths to Total Treated		
	Europeans	Asiatics	Total	Europeans	Asiatics	Total	Europeans	Asiatics	Total
(*a*) 1902	1,159	26,515	27,674	68	4,406	4,474	5·86	61	16·16
(*b*) 1903	1,043	24,324	25,367	45	3,911	3,956	4·31	16·07	15·6
(*c*) 1904	1,163	24,769	25,932	69	3,767	3,836	5·93	15·21	14·79

(*a*) Includes 331 cases and 42 deaths in Lunatic Asylum. (*b*) Includes 400 cases and 55 deaths in Lunatic Asylum. (*c*) Includes 485 cases and 59 deaths in Lunatic Asylum.

Penang and Malacca the general condition may be considered satisfactory, but in the former Settlement fears are also expressed of the water supply running short. In the province improvement goes on slowly but steadily.

(9) *Hospitals and Work done.*—The total number of admissions into the hospitals during 1904, excluding the lunatic asylum, was 23,462 against 23,150 in 1903.

(10) The preceding table shows the work done during the last three years.

(11) The diseases responsible for the greatest number of admissions and deaths are shewn in the subjoined Tables, compared with the corresponding diseases and deaths in 1903.

I.—General Diseases.

Diseases	1903		1904	
	Admissions	Deaths	Admissions	Deaths
Dysentery ..	707	267	723	245
Malarial Fever ..	2,005	151	2,694	205
Beri-beri	1,919	647	2,631	879
Phagedœna ..	234	60	344	67
Tubercle of Lungs	730	408	853	484
Venereal Diseases	1,818	96	1,784	95
Rheumatism ..	1,075	..	823	1
Anæmia	964	262	590	93
Debility	907	339	757	270

II.—Local Diseases.

Diseases	1903		1904	
	Admissions	Deaths	Admissions	Deaths
Diseases of the Nervous System (including admissions to the Lunatic Asylum less cases transferred there from other hospitals)	736	112	651	138
Diseases of the Respiratory System (not including Phthisis)	574	108	496	126
Diseases of the Digestive System (including Diarrhœa) ..	2,028	678	1,646	524
Diseases of the Skin..	2,626	4	2,997	4

III.—Injuries.

	1903		1904	
	Admissions	Deaths	Admissions	Deaths
General and Local	1,557	56	1,831	139

(12) *Operations.*—One hundred and twenty-four operations, returned as such, were performed, with 5 deaths. There were also 226 operations performed in the General Hospital, Singapore, requiring the use of an anæsthetic. These were included in the return under the diseases for which they were admitted, but a separate statement shewing the operations performed is put up.

(13) Six specimens of malignant tumours and growths were forwarded to the Superintendent of the the Cancer Research Fund, London, from Singapore, and seven from Penang.

(14) The recovery rate in the Lunatic Asylum in 1904 shows an improvement over that of 1903.

The Maternity Hospital return shows that good work was done there during the year. One Probationer passed her examination and was granted the usual certificate.

(15) *Quarantine.*—Two hundred and seventy-nine thousand two hundred and ninety-seven crew and passengers were examined on arrival in Singapore, and 4,444 pilgrims on departure. In Penang the numbers inspected were 184,691 crew and passengers and 1,435 pilgrims. There seems to be a great reduction in the number of pilgrims inspected both in Singapore and Penang in 1904 as compared with 1903.

Further needed improvements, details of which will be found in the appendix under Quarantine, were carried out on the Station at St. John's. The Port Health Officer reports that the disinfecting steam lighter *Hygeia*, fitted with a Clayton disinfector, has answered all expectations.

(16) *Out-Door Dispensaries.* — Nineteen thousand nine hundred and seventy patients attended at the various Out-Door Dispensaries in the several Settlements during 1904 as against 18,031 the year previous.

(17) *Vaccination.*—The total number of vaccinations performed throughout the Colony during 1904 was 15,765 as against 15,496 in 1903. The following table shows the number vaccinated, with the results in the several Settlements during 1904.

Settlement	Number of Vaccinations Performed	Result				
		Perfect	Modified	Failed	Unknown	
Singapore ..	2,554	2,551	..	3	..	(*a*)
	1,797	1,631	9	96	61	(*b*)
	376	356	3	17	..	(*b*)
Penang	3,280	2,266	633	177	204	
Dindings	133	44	7	13	69	
Province Wellesley	3,680	2,924	287	452	17	
Malacca	3,945	3,379	72	387	107	
Total ..	15,765	13,151	1,011	1,145	458	

(*a*) By Government Vaccinator. (*b*) By Licensed Vaccinators.

The above do not include vaccinations performed in the prisons or at the Quarantine Stations. Saigon Lymph was used throughout the year. The results, although not very satisfactory, especially in Province Wellesley, appears to be an improvement over those of 1903.

(18) *Staff.*—Dr. G. D. Freer, Colonial Surgeon Resident, Penang, returned from leave on March 5th, relieving Dr. T. H. Jamieson, a private medical practitioner.

Dr. R. Dane, Colonial Surgeon, Singapore, proceeded on long leave to Europe on March 4th, his place being taken by Dr. W. S. Sheppard, Supernumerary Colonial Surgeon.

Dr. J. Catto resigned his appointment as Resident Medical Officer, St. John's, and Assistant Port Health Officer, and was succeeded by Dr. D. M. M. Ross, from England, on March 19th.

Dr. A. L. Hoops was appointed House Surgeon in the General Hospital, Penang, a new appointment, and arrived there from England on June 9th.

Assistant Surgeon H. J. Gibbs returned from long leave on November 18th, after having successfully passed the examinations for the L.R.C.P.Lond., and M.R.C.S.Eng. He also took the certificate in psychological medicine.

Assistant Surgeons M. W. Laporte (Singapore), and S. A. O'Keefe (Penang), retired during the year.

Dr. Edith Boomgardt was appointed Assistant Registering Officer of deaths in Penang in place of Assistant Surgeon O'Keefe, retired. An additional Assistant Surgeonship was sanctioned for the Quarantine Station at Singapore. This was temporarily filled by the appointment of Mr. A. P. Dantes, M.R.C.S., L.R.C.P., whose services were also utilised at the General Hospital as House Surgeon.

The posts of matron and three nurse probationers were added to the Lock Hospital, Singapore, and two nurse probationers to the General Hospital, Penang.

There were several changes among the nursing staff tending much to disorganise good work and discipline.

With the exception of some old hands the dresser staff does not seem to be satisfactory. Although the scheme for salaries has been improved the class of men applying for admission is not promising. This branch of the medical service requires to be strengthened, and I hope, with the opening of the Medical School in the Colony, to have men joining for a lower degree, say, of hospital assistant.

(19) Two Straits Students, Messrs. Sit Peng Lok and B. G. Samy, passed the grade of Assistant Surgeon in Madras, returned to the Straits in 1904, and filled up two posts vacant from the beginning of the year in Province Wellesley and Malacca respectively. At the end of the year there were eleven student apothecaries of the Straits Government in the Madras Medical College. In view of the establishment of a medical school in Singapore no more students will be sent to Madras in future.

(20) The Morphine Ordinance and Opium Ordinance were amended with a view to bringing those dealing in those articles as chemists and druggists under more efficient control, and restricting all unqualified medical men from prescribing the same.

(21) In September, 1904, the Honourable Tan Jiak Kim, a member af the Legislative Council and an influential member of the Chinese community, petitioned the Government on behalf of the Chinese and other communities of this Colony praying for the establishment of a medical school. The Government, notwithstanding the difficulties hitherto experienced in the proposal to establish such an institution, expressed its willingness to sanction such an undertaking, provided the petitioners were willing to pay for the initial cost of same, *i.e.*, for the building and equipment, and raise on endowment fund of $60,000 for the payment of ten scholarships for students of native origin, the Straits Government and the Government of the Federated Malay States undertaking to give five Scholarships each in addition, and paying for the staff and upkeep of the said school. With commendable promptitude Mr. Tan Jiak Kim managed to collect subscriptions far in excess of the amount actually required. All preliminary steps for the establishment of the school have been taken. A Bill constituting the necessary Council will soon be introduced in the Legislative Council, and in a few months hence the school will be an accomplished fact.

May 12th, 1905.

Appendices.

SINGAPORE.

Report by Dr. J. Leask, Colonial Surgeon Resident.

Table A—1.

	Remaining on 31.12.03	Admitted	Total Treated	Discharged	Transferred	Died	Remaining on 31.12.04	Percentage of Deaths to Total Treated
European ..	20	615	635	553	11	42	29	6·61
Natives ..	82	2,169	2,251	1,736	175	261	79	11·63
Native Police..	12	377	389	375	1	1	12	0·25
Totals ..	114	3,161	3,275	2,664	187	304	120	9·28

The work in the wards has been heavy throughout the year, not so much owing to the increase in the number of admissions, which was only 57 over the previous year, as to the large number of daily sick (163·045, the highest on record for this Hospital) and to the large number of Surgical cases in the Native Wards.

Of the General Diseases causing admissions to Hospital, the various manifestations of Malaria come first with 333 admissions and 12 deaths. Next in order are Venereal diseases (including local affections) 298 with 5 deaths, Beri-beri 126 with 41 deaths, Dysentery 120 with 31 deaths, Tuberculosis 108 with 4 deaths, Enteric Fever 76 with 22 deaths, Dengue 45 cases, Debility 32 and 1 death, Anæmia 28 and 1 death, Febricular 20 cases, Tetanus 6 with 4 deaths, Erysipelas 6 with 2 deaths, Pyæmia 4 with 3 deaths, Septicæmia 3 and 3 deaths.

Of the Nervous Diseases, Insanity in its various forms 171, Meningitis 8 cases and 8 deaths were the most noteworthy.

Diseases of the Eye caused 20, of the Ear 15 and Heart diseases 15 admissions with 2 deaths.

Respiratory Diseases.—Pneumonia 42 cases and 15 deaths, Bronchitis 40 and 1 death, Asthma 17 and 1 death and Pleurisy 11 cases were the most noteworthy.

Diseases of the Digestive System.—Diarrhœa 34 cases and 3 deaths, Sprue 18 cases and 2 deaths, Fistula in Ano 17, Constipation 16, Hernia 13 cases and 2 deaths, Hepatitis 13 cases and 2 deaths, Liver Abscess 12 cases and 8 deaths, Appendicitis 12 cases and 2 deaths, Piles 5, and Cirrhosis of Liver 4 cases and 1 death.

Colonial Medical Reports.—No. 21.—The Straits Settlements (*continued*).

Urinary System.—Bright's disease 9 cases and 1 death.

Diseases of Bone.—Periostitis 5, necrosis 5, caries 4, are of interest.

Diseases of Connective Tissue.—Abscess 49, cellulitis 22 cases.

Skin Diseases.—The most numerous of these were: Ulcer 79 and 1 death, and eczema 25.

Injuries.—The most numerous general injuries were: Multiple injury 35 cases with 10 deaths, burns and scalds 31 cases with 8 deaths, heat-stroke 5 cases and 1 death.

Of the 650 local injuries the most important were: Wounds 480 cases with 4 deaths, compound fracture 64 cases with 14 deaths, simple fracture 45 cases with 5 deaths—these last were in cases of fracture of the spine.

Of poisons the more important were: Alcohol 54, opium 5 cases and 2 deaths, lead and mercury 1 case each.

Parasites.—The most numerous were: *Acarus scabiei* 25 cases, mostly in Chinese Sinkehs, and others of interest were *Ascaris lumbricoides* 3, *Ankylostoma duodenale* 7, *Filaria sanguinis hominis*, 6, *Tænia solium*, 4.

After twenty-one years' experience of the Straits, I cannot help being struck by the steady increase of certain diseases during that period, amongst the Asiatic population chiefly.

The first of these is tuberculosis, mostly of the lung. This disease having once got a footing and having found a suitable environment, has steadily spread.

Along with this I find that fistula in ano is becoming much more common, and lately a few cases of disease of bone, hitherto absent, are beginning to appear.

Pneumonia has been making rapid strides during the last few years.

Enteric fever has become common amongst Europeans and natives.

When in 1884 I reported a case of diphtheria my report was received with incredulity, and I was informed that the disease was not known in the Straits. Since then there have been a number of unmistakable cases, many of them fatal.

A warm, moist climate such as this is an ideal one for the breeding of pathogenic micro-organisms, especially in the crowded native quarters, and it remains *a matter of quarantine to keep other infectious germs out.*

It is scarcely necessary to animadvert on venereal diseases, which have always caused a large proportion of admissions to hospital, except that they are probably an important factor in the causation of insanity, yet general paralysis of the insane, as it appears in Europe, is unknown in Asiatics, and locomotor ataxy is rare.

The Asiatic is becoming Europeanised — too much so—stalls for the sale of bread and butter may be seen along the streets; the domestic servant, who would not help himself to any European beverage but brandy and sherry, has now taken quite kindly also to whiskey and beer, and in fact to anything with alcohol in it, very much to his detriment; and now, though the admissions for alcoholism are still mostly in Europeans, there are a few Asiatic admissions from this cause, Chinese, Sikhs, and Tamils.

Three thousand one hundred and sixty-one patients (of whom 220 were females) were admitted, as against 3,104 in 1903, and the total number treated was 3,275, as against 3,233 in 1903.

The average dailynumber of sick was 163·045—the highest on record—as against 130·22 in 1903.

Deaths.—There were 304 deaths (28 among females), 73 of which occurred within a few hours of admission.

The percentage of deaths to total treated was 9·282, as against 9·029 in 1903.

European Wards.—There were 615 cases (of whom 70 were females) admitted to these wards. European members of the Police Force are included in these admissions.

The diseases for which the greatest numbers were admitted were: Venereal diseases 71, malaria 49, alcoholism 39, tuberculosis 31, dysentery 19, rheumatism 10, parasites 10, liver abscess 9, hepatitis 7, appendicitis 6.

Local and general injuries were the cause of 70 admissions.

Zymotic Diseases.—Small-pox 4, dengue 29, mumps 3, enteric fever 22, influenza 1.

Transfers.—There were 11 transfers, 3 to quarantine, 3 to native wards, and 5 to lunatic asylum.

Deaths.—There were 42 (6 being females).

The percentage of deaths to total treated in the European wards was 6·614.

Native Wards (not including native police).—There were 2,169 patients (of whom 150 were females) admitted, as against 2,187 and 141 respectively in 1903.

The diseases for which the largest numbers were treated were: Malaria 235, insanity 162, beri-beri 118, venereal diseases 140, dysentery 86, tuberculosis 67, ulcer 63, abscess 39, pneumonia 35, anæmia 24, diarrhœa 23, bronchitis 20, rheumatism 20, fistula in ano 15, alcoholism 12, constipation 12, debility 21, heart diseases 11, asthma 11, hernia and sprue, each 10, Bright's disease 7, hepatitis 6, appendicitis 5, abscess liver 3.

Local and general injuries were responsible for 630 admissions.

Zymotic Diseases.—Enteric fever 52, dengue 12.

Five Chinese patients developed beri-beri in the ward while under treatment for other diseases respectively 14, 19, 71, 111 and 115 days after admission.

Deaths.—There were 261 deaths (22 of whom were females) among patients treated in the native wards; 65 died within a few hours of admission.

The percentage of deaths to total treated was 11·63.

The number of native private patients depositing money in advance to defray hospital expenses was 662, as against 778 in 1903.

Native Police.—There were 377 admissions, as against 353 in 1903.

The causes of admission were: Venereal diseases 79, malaria 49, malingering 40, bronchitis 16, ulcer 15, dysentery 15, tubercle 10, rheumatism 10, beri-beri 6, pneumonia, asthma, varicose veins and sprue, each 4, alcoholism 3, local and general injuries 21.

Zymotic Diseases.—Dengue 4, small-pox 1, chicken-pox 1, enteric fever 2, and influenza 4.

Transfers.—One to quarantine camp.

Absconders.—There were 58, mostly Malays.

Deaths.—One Malay died of beri-beri.

Percentage of deaths to total treated, ·25.

Medico-legal Work.—There were 1,242 cases sent to hospital by the police for examination or admission, as against 914 in 1903.

There were 57 dead bodies sent for *post-mortem* examination by the coroner, as against 76 in 1903.

There were 189 persons sent to hospital for observation as to sanity, as against 161 in 1903.

My observation with regard to sending these to the General Hospital in my report for 1903 holds good for 1904.

Operations.—There were 226 surgical operations, requiring the administration of a general or local anæsthetic, performed during the year.

The most numerous and interesting were: On tumours 3, abscess 31, excision of glands 23, removal of sequestra 13, excision of shoulder 1, amputations 20, trephining skull 2, harelip 1, enucleation eyeball 5, suturing divided tendons 3, paracentesis thoracis 1, excision of ribs for empyema 1, exploratory puncture of liver 2, gastrostomy (Francke's) 1, hepatic abscess, 12, abdominal section for suturing wounded intestine 3, strangulated hernia 9, hernia radical cure 2, typhlitic abscess 1, fistula in ano 12, circumcision 17, hydrocele radical cure 3, removal lymph scrotum 1, elephantoid labium 1, curetting uterus 3, ovariotomy 1, abdominal section for pelvic hæmatocele 2.

During the last twenty-four years it has been my practice to give from 25 to 30 minims of tincture of belladonna a quarter of an hour or twenty minutes before the administration of chloroform, and I have had no case of death from chloroform in my practice during all these years. The active principle of this drug has a paralysing action on the cardio-inhibitory fibres of the vagus and so prevents reflex inhibitory impulses from affecting the heart's action.

As an Asiatic will just as soon part with his life as with a limb, a great deal of the surgery in this hospital is necessarily ultra-conservative, and the death-roll is consequently heavy, and stay in hospital long. On the other hand, the most wonderful recoveries take place sometimes.

Staff.—I have been in charge throughout the year.

House Surgeons.—Dr. Ford and Dr. Barrack have been house surgeons, and on September 1st, Mr. A. P. Dantes, M.R.C.S., L.R.C.P.Lond., assistant surgeon, took duty in addition as acting house surgeon, thus placing a great deal more time for purely professional work at the disposal of the house surgeons.

It would be to the advantage of the hospital to have three house surgeons permanently, there being too much work for two.

In the subordinate staff I have to record numerous changes again, militating against the efficiency of the hospital.

Police Force.

Report by Dr. W. G. Ellis, Police Surgeon.

The total number of the force attending the out-patient room at the Central Station was 4,096, as compared with 3,478 for 1903, and 4,305 for 1902. More of these than is usual were malingerers, and when it could be definitely brought home to them they were reported and punished. Latterly I have sent many of those whom I considered to be malingering to hospital for observation, where they were detained for a few days and so lost their pay, and the crime is now diminishing.

The greatest number seen on any one day was 34, the lowest 2.

The average daily number attending shows a slight increase over the previous year; it was as follows:—

Month	1899	1900	1901	1902	1903	1904
January ..	32·72	17·69	14·12	12·92	12·08	11·83
February ..	23·95	18 33	12·55	11·70	15·90	11·62
March	29·76	18·15	13·73	11·12	11·72	12·11
April	28·04	18·02	14·86	17·10	12·14	11·12
May	28·57	19·01	12·34	17·32	11·68	14·52
June	25·65	22·64	12·33	17·70	13·74	15 61
July	23·03	18·72	11·77	15·00	12·18	15·07
August ..	22·37	18·97	12·65	12·05	11·08	11 88
September ..	28·65	16·04	13·08	14·00	10·46	12·69
October ..	29·19	21·93	12·66	14·10	10·25	16·46
November ..	26·65	21·50	13·2	14·10	10 63	13 57
December ..	25·84	18·91	13·08	16·22	10·30	14·32

Of the out-patients seen, 357 were sent to hospital as in-patients, compared with 556 sent to hospital in 1899, 290 in 1900, 294 in 1901, 350 in 1902, and 317 in 1903. Others of the force have been admitted to the General Hospital for treatment, having been sent by inspectors as urgent cases; of these I have no records.

The 357 were suffering from the following disorders: Unclassed fevers 65, intermittent fever 5, dengue 10, enteric fever 2, dysentery 10, diarrhœa 17, beri-beri 12, phthisis 4, bronchitis 16, pneumonia 1, appendicitis 1, Bright's disease 2, rheumatism 11, syphilis 40, gonorrhœa 37, cellulitis 20, synovitis 5, ulcers 8, minor injuries 9, hydrocele 3, eye and ear affections 9, skin diseases 6, tape-worm 3, alcoholism 4, debility 9, malingering 48.

During the year there have been 70 cases of beri-beri, with 2 deaths, and necessitating the invaliding of three men from the service. Nearly all of these cases occurred in the Central Station in the months of June and July. This station at the time was much overcrowded, men using the same beds in relays, and no proper attention was paid to cleanliness. The cessation of the overcrowding, a thorough clean up, and the regular use of disinfectants, quickly bore fruit, though a few odd cases continued to occur until nearly the end of the year. The cases were mostly slight, and coming under observation early soon recovered upon being transferred to the seaside stations.

Three hundred and thirty-three candidates for the force were examined during the year; of these 262 were passed as fit, and 71 were rejected.

The causes for rejection were as follows: Over age 4, ill-development 24, phthisis 8, hernia 2, anæmia 4, heart disease 9, enlarged spleen 7, hydrocele 1, venereal diseases 8, and impaired vision 4.

The nationalities were: Twelve Europeans passed and none rejected, 117 Malays passed and 35 rejected, 52 Sikhs passed and 14 rejected, 37 Indians passed and 12 rejected, 30 Chinese passed and 8 rejected, 5 Eurasians passed and none rejected, and 9 Sikhs passed for re-engagement and 2 rejected.

The sanitary conditions of the 35 stations are fairly satisfactory, and several minor improvements have been completed during the year. Details of inspections, with my suggestions, are made in a book which is forwarded to the Chief Police Officer from me to time.

Prison Hospital.

Report by Dr. J. Leask, Colonial Surgeon in Charge.

The sanitary condition of the prison was fair, and was further improved during the year.

I mentioned in my report for 1903 that more ventilation was required for the cells and in the Middle Grade Work Yard.

Dr. C. W. Daniels, Director of the Institute of Medical Research, Federated Malay States, visited the prison in February and reported on its sanitary condition, making certain recommendations.

The following additions and alterations were carried out:—

(*a*) Perforated iron plates were inserted at the bottoms of the cell doors, giving better floor ventilation.

(*b*) Iron weather-boards were fixed over the cell windows, and the wooden boards placed inside the windows in wet weather were done away with. In some instances, notably at the punishment cells, these plates have been too much sloped, cutting off too much light.

(*c*) The bathing tanks were separated from the latrines, thus doing away with a possible source of contamination of water, as prisoners *will* drink from the bathing tanks when not watched.

(*d*) The latrine in the kitchen, also contiguous to a water-tank, was done away with, and a more sanitary arrangement made outside the kitchen.

(*e*) A new set of water-pipes was laid throughout the prison, away from the drains, doing away with another possible source of water contamination.

(*f*) The cement work of the prison was relaid throughout, with the exception of the interiors of the halls. When newly laid down this work has been so slippery that a number of accidents have occurred—two warders slipped and broke their arms, and quite a number of falls amongst warders and prisoners have occurred.

(*g*) The flat parts of the roofs of the blocks were sloped and extra down pipes fixed in order to carry away storm water more rapidly.

(*h*) Iron gratings were substituted for honeycomb brickwork in the arches under the blocks. These are hinged and locked so as to give access for cleaning purposes.

(*i*) The flattened roof ends of the worksheds and wheelhouse were carried out as open gable ends, and this has produced a marked improvement in the air of these places.

(*j*) An allowance of soap is now being issued to the prisoners for body cleansing.

(*k*) The substitution of brick for corrugated iron partitions between the cells is being carried on steadily, but not very carefully, as I notice numerous crevices at the angles of the cells.

In spite of all improvements three cases of enteric fever occurred, two of whom must have contracted the disease in the prison; dysentery has been prevalent; one case of what was clinically cholera occurred, and beri-beri cases have increased in numbers.

The health of the prisoners during the year was not satisfactory. Although there were fewer admissions to hospital (1,009, as against 1,041 in 1903) the average daily sick was much higher (72·47, as against 44·96 in 1903) and the number of deaths was greater than during the previous year.

There were 52 deaths in hospital, as against 45 in 1903 and 38 in 1902, giving a death-rate of 48·01 per mille of total treated, as against 40·7 in 1903 and 26·04 in 1902.

Out of 3,052 male prisoners examined on admission, 1,146 showed signs of present or past venereal disease, as against 916 in 3,272 admissions in 1903.

Diets.—Bengal rice, *i.e.*, rice which has gone through a process of malting, was given instead of Siamese rice on November 1st (except for congee making, for which it was unsuitable).

Births.—A Chinese short sentence prisoner was delivered of a child in February.

Work done in Hospital.—There were 74 patients remaining in hospital on December 31st, 1903; 1,009, of whom 10 were females, were admitted during 1904, giving a total treated of 1,083. Of these, 936 were discharged, 30 transferred to Malacca, 52 died, and 65 remained on December 31st, 1904.

The diseases responsible for the greatest number of admissions were:—

Beri-beri	...	266 cases, as against 169 in 1903 and 415 in 1902.
Fevers	...	163 cases, as against 163 in 1903 and 188 in 1902.
Dysentery	...	136 cases, as against 104 in 1903 and 156 in 1902.
Dyspepsia	...	87 cases, as against 43 in 1903 and 66 in 1902.
Diarrhœa	...	67 cases, as against 112 in 1903 and 186 in 1902.

Deaths.—There were 52 deaths, as against 45 in 1903. The causes of death were dysentery 19, beri-beri 17, pulmonary tuberculosis 7, heart disease 2, cholera, enteric fever, cancer of stomach, fibroid phthisis, enteritis, compound fracture of thigh and cerebral hæmorrhage in beri-beri patient 1 each.

Beri-beri.—Instead of exacerbating towards the end of the year, as it did in 1903, this disease quickly declined from September, as shown in the subjoined comparative table.

In the first quarter of the year there were 63 admissions and 2 deaths, in the second quarter 55 admissions and 3 deaths, in the third quarter 108

TABLE A—2.

SHOWING THE ADMISSIONS AND DEATHS MONTHLY SINCE THE BEGINNING OF THE OUTBREAK.

Month	1897		1898		1899		1900		1901		1902		1903		1904

	3	..	124	1	165	2	224	28	219	9	415	11	169	16	266	17

admissions and 10 deaths, and during the fourth quarter 40 cases and 2 deaths.

The third quarter was therefore the most unhealthy as regards beri-beri this year, and in consequence of the large numbers overcrowding the hospital, 30 cases of beri-beri were sent to Malacca on October 6th.

There were 266 admissions and 17 deaths, as against 169 admissions and 16 deaths in 1903, giving the percentage of deaths to total treated as 6·7, against 9 4 in 1903.

Grades Affected.—One hundred and fifty-three cases of beri-beri occurred among short sentence prisoners, 68 among middle, 21 among lower, 15 among revenue, and 5 among upper grade prisoners: 3 cases occurred in prisoners undergoing simple imprisonment and one in a civil prisoner.

Nationalities attacked by Beri-beri.—Chinese 229 with 15 deaths, Malays 28 with 1 death, Indians 8 with 1 death, and Filipino 1.

Sexes attacked by Beri-beri.—In the correspondence in the *Times* newspaper on the Chinese coolie question in South Africa it was stated by a medical writer that females were immune from beri-beri. There were 6 well-marked cases of beri-beri in female prisoners in 1904, 1 Chinese and 5 Malays. In 1900 there were 7 female cases; in 1901, 1 Chinese; in 1902, 1 Chinese; in 1903, 1 Malay.

Length of Imprisonment of those Attacked.—Of the 266 admissions, 51 were primary attacks occurring in prisoners under three months in prison; 87 were primary attacks occurring in prisoners over three months in prison; 5 were recurrences occurring in prisoners under three months in prison; 52 were recurrences occurring in prisoners over three months in prison; 10 were admitted suffering from the disease, and 61 had a previous history of having suffered from beri-beri outside the prison.

Deaths from Beri-beri.—There were 17, and one beri-beri case died of cerebral hæmorrhage and softening. Of these, 14 were short sentence, two middle and one lower grade prisoners.

TABLE A—3.

TABLE SHOWING THE INCIDENCE OF BERI-BERI IN THE DIFFERENT GRADES, SINCE THE BEGINNING OF THE OUTBREAK.

Grade	1897	1898	1899	1900	1901	1902	1903	1904	Total
Upper	..	7	6	9	13	19	9	5	68

* Included under Grades.

Colonial Medical Reports.—No. 21.—The Straits Settlements (*continued*).

Dysentery.—There were 136 admissions and 19 deaths, as against 104 with 13 deaths in 1903. The disease continues to be of a severe type, and ipecacuanha in large doses, with intestinal irrigation (alkaline in the early stages, and of nitrate of silver ½ grain to one ounce in later and more chronic cases), have given the most satisfactory results.

Post-mortem examinations in the fatal cases have shown the same deep necrosis of tissue mentioned last year.

Grades Attacked.—Short sentence 62 cases, middle grade 33, lower grade 22, revenue grade 7, upper grade 3, remand prisoners 4 (simple imprisonment 3), and 2 prisoners from banishment.

Nationalities.—Europeans 2, Chinese 93 with 12 deaths, Malays 27 with 1 death, Indians 13 with 5 deaths, Anamite 1 died.

Dyspepsia.—This has been more prevalent this year, causing 87 admissions, as against 43 in 1903. Fissured tongues and cracked lips, and an eruption of lichen planus are also making their appearance.

Zymotic Diseases.—One case of chicken-pox and one case of measles occurred in short sentence prisoners. The former case probably contracted in prison, and the latter probably came into prison with the disease in the period of incubation.

Cholera.—One Chinese short sentence prisoner contracted cholera after having been over three months in prison, and died within a few hours. Clinically, it was a typical case, but the bacteriological examination was negative.

Enteric Fever.—There were 3 cases during the year.

The first was that of a European short sentence prisoner who was committed to prison on July 22nd, and admitted to hospital on August 2nd, having been feeling unwell for eight or ten days before.

The second case was a Chinese lower grade No. 164, committed to prison March 1st, and admitted to hospital December 13th. The source of infection was probably outside the prison.

The third case was a Chinese lower grade No. 175, committed to prison March 16th, and admitted to hospital December 21st.

The European and one of the Chinese (No 175) recovered, and the other Chinese (No. 164) died.

In the two latter cases Widal's reaction was positive.

In the fatal case the *post-mortem* appearances were very well marked.

There was one case of mumps.

In none of these infectious cases could the source of infection be traced.

Tan Tock Seng's Hospital.

Report by Dr. W. S. Shepherd, Acting Colonial Surgeon.

Buildings.—Only such repairs as were absolutely necessary have been executed during the year, owing to the prospect of an early removal of the hospital to a new site.

The usual whitewashing and tarring were performed twice during the year by the Public Works Department.

Grounds.—The digging of long trenches in many places leading into the main drains has done much to improve the drainage of the grounds.

The hospital is to be congratulated on having obtained the services of Dr. Finlayson as Pathologist. He now conducts the autopsies in all cases except those of medico-legal interest.

Statistics.—The total number of patients treated and the death-rate are set down in Table I., which also gives the figures for the preceding nine years. The death-rate—22·4 per cent.—is a little below the average.

A certain number of admissions are readmissions, as stated in last year's report. It is not easy to estimate this number, as patients when seeking readmission frequently give a new name.

The average daily number was 571.

Table II. gives the diseases for which admission was chiefly sought in 1904 and the previous four years, also the number of deaths from these diseases.

Beri-beri.—One thousand one hundred and twenty-five cases were admitted, as against 975 in 1903. I am inclined to attribute to this increase in our numbers the increase in our death-rate from this disease—46 per cent., as against 36 per cent. in 1903. Our beri-beri wards were undoubtedly too crowded, but there seemed no option between admitting the sick and sending them back to their houses to die. Many of our admissions under this head were cases brought in by the police, who could not be refused admission. A certain number of cases about 60—appeared to have originated in the hospital; but owing to the difficulty of diagnosing latent beri-beri it is not possible to estimate this number with exactness.

During the year trial was made of potassium permanagate as a remedial agent, this drug being administered in two-grain doses twice daily. No good appeared to follow this treatment and after a few months it was discontinued. Our experience seems to indicate that a milk diet is best for this disease. Blisters over the pericardium appear to relieve the distressing cardiac dyspnœa better than any other treatment.

Fevers.—There were 617 cases of malarial fever, 245 cases being of the benign and 372 of the malignant variety. The prevalent benign form is tertian, not more than a dozen cases of quartan occurring in the year. Twenty per cent. of malignant and seven per cent. of the benign cases proved fatal, many of the patients being brought in in a comatose condition by the police.

The intramuscular injection of quinine has been practised in all cases when a rapid result was desirable. No ill-effects have been recorded in a single instance.

There were 70 cases of enteric fever with 36 deaths, as against 11 cases with 7 deaths in 1903. The high mortality rate is due to the lack of skilled nursing and to the fact that the patients are so often brought to hospital in a dying condition.

Fourteen major operations were performed, mostly amputations of the leg for large intractable ulcers.

General Remarks.—During the year I have found it necessary to institute the following changes:—

To set apart a separate staff of dressers for night duty. Hitherto continuous night and day duty has been expected of the dressers, an obviously impossible expectation.

The only drawback to the present system is that it depletes our already very insufficient day staff.

Two senior dressers have been set apart, one for dispensing, the other as steward.

To attempt to locate the dresser to the wards under his particular care. To this end, a table and a chair have been given him in one of his wards, and the dressers' room, situated too far away from the wards to be useful, has been converted to another purpose.

A system of diet indent book wherein the dresser writes his indent each afternoon for the succeeding day. This secures a permanent record, by which expenditure can be checked by myself.

A daily roll-call of the attendants has, indirectly, done much to lessen the number of those running away after each pay day.

An attendance book has been placed in each ward for recording the time and duration of the assistant surgeons' and dressers' visits.

The large staff of ward attendants, coolies, barbers, toties, &c., amounting to about seventy men in all, has been struck off the list of patients. Our daily average number of patients is thus less by this number.

QUARANTINE CAMP.

(1) SMALL-POX.

	Remained	Admitted	Total	Discharged	Died	Absconded	Remaining
Male	1	19	20	13	2	1	4
Female ..	..	6	6	4	2	..	..

Of those treated, 8 were Chinese, 6 Tamil, 6 Malays, and 6 miscellaneous.

(2) BUBONIC PLAGUE.

	Remained	Admitted	Total	Discharged	Died	Absconded	Remaining
Male	..	8	8	..	8	..	..
Female ..	..	3	3	..	3	..	..

Of these cases, 8 were Chinese, 1 Tamil, and 2 Bombay men.

(3) DIPHTHERIA.

	Remained	Admitted	Total	Discharged	Died	Absconded	Remaining
Male	..	3	3	1	2	..	..

Two were Chinese, and 1 Arab.

LEPER ASYLUM.

	Remained	Admitted	Total	Discharged	Transferred	Absconded	Died	Remaining
Male ..	15	59	74	9	22	2	31	10
Female	20	6	26	..	..	..	6	20

The sanitary condition of the asylum was good.

The space allotted to the females is, however, very limited. The nine males discharged were handed over to the care of their relatives by order of the magistrate.

LUNATIC ASYLUM.

Report by Dr. W. G. Ellis, Medical Superintendent.

The average daily number of patients resident during the year was 268 (males 213, females 55), an increase of 53 males and 6 females as compared with the previous year.

On December 31st, 1903, there remained 231 patients (males 179, females 52). There were admitted in 1904, males 223, females 31, making the total treated 402 males and 83 females. The maximum

and minimum numbers in the asylum on any one day of the year were respectively 305 and 229.

Of the 283 patients remaining on December 31st, 1904 :—

Males.	Females.	Total.		
151	35	186	came from	Singapore.
39	11	50	,, ,,	Penang.
8	3	11	,, ,,	Province Wellesley.
15	1	16	,, ,,	Malacca.
5	—	5	,, ,,	British North Borneo.
1	—	1	,, ,,	Labuan.
12	1	13	,, ,,	Negri Sembilan.
1	—	1	,, ,,	Johore.

There were 12 criminal lunatics and 2 lunatic criminals under treatment on December 31st, 1903; 9 criminal lunatics and 8 lunatic criminals were admitted during the year, making a total of 31 criminals treated; of these three were discharged recovered, 6 on expiry of sentence were transferred as ordinary patients, 4 died, and 14 criminal lunatics and 4 lunatic criminals remain under treatment.

Evidence of past and present venereal disease in the admissions, as in previous years, is common. Over 24 per cent. had suffered from syphilis, a percentage that has gradually increased from the 13·48 per cent. of the 1896 admissions. Syphilis was the undoubted cause of the insanity in many of the cases, and was the cause of death in 8 cases, 3 being due to gumma in the brain.

Beri-beri.—From October 13th, 1903, to October 13th, 1904, all patients were fed on the cured Bengal rice, and during this period but one case of beri-beri occurred in the asylum, a case attacked early in November, 1903. During this same period the disease was epidemic in the Singapore gaol, and formerly when epidemic in the one institution it was invariably epidemic in the other. On October 13th, 1904, we returned to the uncured Siam rice, and in December 15 cases of beri-beri arose, coming from all parts of the asylum, though none occurred amongst the 20 males and 8 females kept on Bengal rice as controls. I am far from being convinced that the consumption of the uncured rice is the cause of beri-beri, and have yet several experiments to complete; but my experience of the past few years, since making researches into the subject, certainly tends to make me far less antagonistic to the theory than formerly. My work is not yet ready for publication, but shortly I trust to have some results to bring forward.

In the early part of the year some of the underground drains in the lower levels of the asylum became blocked, and at the same time an epidemic of dysentery and diarrhœa broke out. In all there were 47 cases of bowels diseases with 9 deaths. The drains, after some delay, were dug up, substituted by surface drains, and the health of the asylum improved.

Towards the end of the year the asylum became considerably overcrowded, a possible factor in the outbreak of beri-beri, and the health of the patients suffered, many being attacked with dysentery and diarrhœa.

I am happy in being able to state that it has been decided to construct a new asylum upon modern and sanitary lines as soon as possible, and an excellent site with sufficient land for a farm has been chosen.

Admissions.—Two hundred and twenty-three males and 31 females have been admitted during the year; of these, 22 males and 7 females were readmissions.

One hundred and sixty-six males and 24 females came from Singapore, 21 males and 2 females from Penang, 17 males and 1 female from Malacca, 4 males and 3 females from Province Wellesley, 11 males and 1 female from Negri Sembilan, and 4 males from British North Borneo.

The physical condition of those admitted was in a large number of cases deplorable, as is usual here. Of the 254 admissions, 85 were chronicled as physical condition impaired, and 47 as greatly impaired. Of these latter, 15 died before they had been in residence a month.

Discharges.—One hundred and four patients have been discharged recovered, equal to a recovery rate of 40·94 on the admissions. This is a marked improvement upon last year, and must be considered satisfactory.

Twenty-three patients were discharged relieved and 11 not improved to the care of their friends. A far larger number of patients are fit to be discharged in this way, but their friends and relatives are in China, and we have no means of communicating with them.

Deaths.—Forty-eight males and 11 females died during the year. The percentage of deaths on the average number resident was 22·01, the lowest since 1893.

Forty *post-mortem* examinations were held and the results recorded.

Industries.—During the year there have been manufactured 3,792 yards of cloth and 33 blankets. From the cloth there have been made 745 pairs of trousers, 656 jackets, 261 women's jackets, 163 sarongs, and 108 dusters.

About 80 per cent. of our inmates are usefully employed, every encouragement in the way of small luxuries such as tobacco, fruit, &c., being given them to this end.

Maternity Hospital.

Report by Mr. N. A. Wray, Assistant Surgeon in Charge.

The buildings are in good order. Four additional dwelling-rooms were erected during the year for servants.

Whitewashing, tarring and painting were carried out during the year.

Dr. Fowlie continued to render his valuable services to the hospital.

Mrs. Hennessy, the matron, has done very good work.

One probationer, Mrs. Massabini, passed her examination and received a diploma as midwife. Mrs. White is still under training.

The number of admissions (72) shows a decrease of 13 on last year, but as the hospital was closed from March 23rd to May 23rd owing to a case of septic-

æmia occurring in the hospital, the numbers compare favourably with previous years.

The following table shows the work done during the year:—

Nationality	Remained	Admitted	Total	Discharged	Died	Remaining
Europeans ..	1	28	29	29	..	..
Eurasians ..	..	4	4	4	..	..
Tamils ..	3	25	28	28	..	..
Chinese ..	..	10	10	8	2	..
Hebrew ..	..	4	4	4	..	..
Singhalese ..	..	1	1	..	1	..
Total ..	4	72	76	73	3	..

The three deaths were due to (1) septicæmia, (2) shock on rupturing membranes in a case of placenta prævia, and (3) from beri-beri and peritonitis, the patient, a Chinese, having been, it was said, in labour for nine days before seeking admission.

The average daily number in hospital was 2·02.

Of the 66 labours in hospital, 53 were natural, 4 were difficult, 8 were preternatural, and one was complex.

There were 3 cases of placenta prævia. The first, a Singhalese lady, died of septicæmia, the second, a Chinese, succumbed to shock, on rupturing the membranes, and the third, a European, came in early and made a good and rapid recovery.

There was one case of foot presentation and one of breech. There were also one case each of partial inversion of the uterus and premature detachment of the placenta. Forceps were used in three instances. There was one case of abortion in the fifth month.

Hæmorrhage occurred in five cases, three unavoidable (placenta prævia) and two accidental (partial inversion of the uterus and premature detachment of the placenta).

Of the 66 births, 57 children were born alive, 8 were stillborn and 1 prematurely, the sexes being 30 males and 36 females.

PENANG.

Report by Dr. T. C. Mugliston, Colonial Surgeon.

The public health of Penang for 1904 has been up to the average of previous years, and judging from the total number of deaths registered and by the death-rate per mille of the estimated population, though not so good as 1903, was better than that of the year 1902.

The total number of deaths registered was 5,517, as against 4,988 in 1903, and 5,787 in 1902; of the total number of deaths registered, 4,222 were within municipal limits and 1,295 in country districts. On an estimated population of 130,602, this gives a crude mortality of 42·24 per mille. Eliminating the deaths at Pulau Jerejak (Leper Asylum 140, quarantine station 6, and of those dying shortly after arrival in the colony, 309; town 279, country 30), the corrected death-rate for the island comes to 38·75; 40·49 per mille for the population within municipal limits, and 38·06 per mille for the country.

Zymotic disease in epidemic form was absent; small-pox, 3 cases only occurred in the town; 16 cases were imported and removed from vessels; of these 19 cases, 7 died. Chicken-pox—there were 66 cases (8 cases imported); measles 9 cases.

Cholera.—No cases were reported; 5 cases were imported and treated on Pulau Jerejak.

Enteric Fever.—One hundred and thirty-eight deaths were registered. According to hospital statistics, there were 10 admissions, with 6 deaths.

Plague.—Two cases occurred among a ship's crew, both cases were removed to the quarantine station, Pulau Jerejak, and died; the diagnosis was confirmed bacteriologically. No cases occurred in the town or country.

The infant mortality for 1904 was rather high, the number of infants dying under one year being 704, or 12·75 per cent. of the total number of deaths registered, and 28 per cent. of the total number of births registered. Referring back to the records for ten years, the number of infants dying last year is the highest, while the percentage to the total number of deaths registered comes second to the year 1899. Tetanus neonatorum accounts for about 19 per cent. of those infants dying under three months.

On the retirement of Assistant Surgeon O'Keefe on pension, Dr. Edith Boomgardt, L.R.C.P. & S.(Edin.), &c., was appointed Deputy Registrar of Deaths. During the first three quarters of the year 1904 the percentage of unclassified "fever" cases to the total number of deaths registered in municipal limits approximated 3·84 (first quarter 1·30 per cent., second quarter 1·26 per cent., third quarter 1·28 per cent.); in the fourth quarter, the percentage of such "fever" cases to the deaths registered in municipal limits is ·78. Under the present careful investigation the vague item of "fever" is much curtailed, and returns are much better and fuller than formerly, and more care is taken in arriving at the cause of death. I have only referred to deaths within municipal limits; the majority of deaths (nearly 95 per cent.) registered in country districts are returned as "fever." If these unclassified "fever" cases, which are returned by the police, are eliminated, it will be seen that the number of unclassified "fever" cases in the town is almost *nil*.

General Hospital.

Report by Dr. G. D. Freer, Colonial Surgeon, Resident.

The total number of cases treated was 2,117, and the number of deaths 86, as compared with 1,866 and 87 respectively for the previous year.

The average daily sick was 58·53, and the percentage of deaths 4·06.

European Wards.—There were 208 admissions in all, of whom 26 were females. The chief diseases treated were malarial fever 51, venereal disease 14, dengue 11, typhoid fever 5, diarrhœa 5, pneumonia 2, bronchitis 2, injuries 5, alcoholism 6.

Native Wards (excluding police).—The number of admissions was 1,171 (females 104) and deaths 72. The chief causes of admission were: Injuries 396, malarial fever 127, mental diseases 88, venereal diseases 69, alcoholism 46, ulcers 44, beri-beri 30, diarrhœa 25, dysentery 22, bronchitis 28, pneumonia 18.

Colonial Medical Reports.—No. 21.—The Straits Settlements (*continued*).

One hundred and thirty-five Indian immigrants were sent for treatment from the Indian Immigration Depôt, and sixty-five Sinkehs from the Chinese Protectorate.

Eighty-two cases were sent for observation as to sanity, of whom 21 were transferred to the Lunatic Asylum, Singapore.

Native Police (including Malay States Guides).—The admissions numbered 686, against 495 for the previous year, and were made up as follows: Sikhs 355, Malays 297, Hindus 28, Chinese 6; of the Sikh admissions, 104 were from the detachment of Malay States Guides.

The principal diseases among them were malarial fever, 157; dengue, 45; venereal disease, 48; ulcers, 42; bronchitis, 34; dyspepsia and constipation, 31; diarrhœa and dysentery, 10; injuries, 19; pneumonia, 4. There were two deaths from pulmonary tuberculosis and malarial cachexia respectively.

Two hundred and thirty recruits were sent for examination, 155 were passed and 75 rejected.

Eighty men were boarded as unfit for further service.

Dengue.—Out of a total of 71 cases admitted to the General Hospital, 64 were in the months of June, July, and August. Among the police stationed in the Fort it was at one time exceedingly prevalent, hardly a man escaping, and it is interesting to note that out of the total (71), 45 cases were Sikh police stationed in the Fort, while from the Malay States Guides stationed at Sepoy Lines there were only two admissions; also, out of 11 European admissions, 8 were policemen living in the Fort. At the same time, although these cases were not specially isolated in hospital none of the other patients nor any members of the hospital staff contracted the disease. The above rather points to the conclusion that dengue is not infectious in the ordinary meaning of the word, and is in favour of Dr. Harris Graham's theory (mentioned in Manson's "Tropical Diseases") that, like malaria and yellow fever, dengue is communicated by a species of mosquito acting as an intermediary. No doubt the Fort moat forms an excellent breeding ground for many species of mosquitoes. There were no deaths from the disease.

Malaria.—As usual both in the general and pauper hospitals, malaria accounted for a large number of the admissions, and in many of these the diagnosis was confirmed by a microscopical examination. Out of a hundred consecutive fever cases, mostly Chinese pauper patients, I find that malarial parasites were found in 51. In 3 of these crescent bodies only were found; in 16 crescent and small signet ring parasites, in 24 small signet ring bodies only, in 4 benign tertian parasites, and in 4 benign quartan parasites. Out of the 51 patients in whom malarial parasites were found, 16 were found to have marked enlargement of the spleen, but in 20 of the others in whom no parasites had been found, the spleen was also found to be enlarged. From several of the latter specimens were obtained by splenic puncture and stained with a view of showing the Leishman-Donovan body, but in no case so far has this been discovered.

Operations.—The principal operations performed included: Excision of hip-joint, 1; amputation of thigh, 2; thoracotomy with excision of ribs for empyema, 3 (1 died); for abscess of liver, 5 (3 died); removal of tumour, 8; excision of lower jaw, 1; ligature of femoral artery, 3; trephining of skull, 2 (1 died); radical cure of hernia, 1; radical cure of hydrocele, 2; for strangulated hernia, 2 (1 died); external urethrotomy (Wheelhouse), 6; partial excision of rectum, 1; excision of eye-ball, 3; tracheotomy, 1; extraction of lens for cataract, 5; altogether 88 operations were performed under chloroform.

New Growths.—Seventeen cases of new growths were admitted into the general and pauper hospitals during the year. Specimens from seven of them were forwarded to the Cancer Research Society, but so far no report has been received as to their nature. The following are the probable diagnoses with the nationalities of the patients:—

Sarcoma of neck ...	5	all Chinese.
Sarcoma of orbit ...	1	Chinese.
Carcinoma of liver ...	1	Eurasian.
Carcinoma of pancreas	1	Eurasian.
Carcinoma of rectum	1	Hindu.
Epithelioma of penis	3	2 Hindus and 1 Chinese.
Epithelioma of lip ...	1	Malay.
Epithelioma of sebaceous cyst of scalp	1	Chinese.
Fibroma of breast ...	1	Chinese.
Fibroma of thigh ...	1	Sikh.
Hernia testis (probably gummatous) ...	1	Chinese.

Medico-Legal.—One hundred and thirty-six bodies were sent for *post-mortem* examination and inquest. I am glad to say that since the completion of the new "Morgue" in December, dead bodies are now sent there instead of to the hospital mortuary, a most desirable change for many reasons.

Prison Hospital.

Report by Dr. T. C. Mugliston, Colonial Surgeon.

During the year there were 4,705 admissions into prison, as against 3,674 for 1903, the daily average prison population being 421·92.

The admissions to hospital, excluding these detained under forty-eight hours for trivial complaints or observation numbered 155, giving an average daily sick of 6·97, and a daily sick rate of 1·65 of the prison strength.

There were 11 deaths in the prison during the year (five in the first three quarters and six in the last quarter) which is equivalent to a mortality of 7·09 per cent. of those admitted to hospital and 2·34 per mille of the admissions to prison.

The 11 deaths were due to the following causes:—

Malarial fever	1
Phagedæna	1
Debility	5
Tubercular phthisis	2
Chronic diarrhœa	2

Of the total admissions to the prison, 296 bore traces of or were actually suffering from venereal disease; 285 prisoners showed marks of a course of morphia injections, and 76 were confirmed opium smokers.

Vaccination of all prisoners who had not been previously vaccinated or revaccinated, or who bore no marks of a previous attack of small-pox, was performed this year on 423, with a percentage of 80·77 successful cases to total vaccinated.

Vaccine lymph from Saigon was used in all cases.

Pauper Hospital.

Report by Dr. G. D. Freer, Colonial Surgeon Resident.

Buildings.—New quarters for the senior dresser were built during the year. The attap roof of Ward 3 was replaced by a tiled one, the wooden supports replaced by brick pillars, and the floor renewed. The floors of Wards 2, 9, and 10 were reconcreted and cemented, and the wooden flooring of ward and verandahs in the pauper female ward replaced by solid concrete and cement.

Staff.—I took over charge from Dr. Jamieson on March 5th, on my return from leave. Assistant Surgeon C. T. de Souza was transferred to Malacca on July 23rd, being replaced by Assistant Surgeon C. J. Bateman on August 15th, Assistant Surgeon T. J. Scully acting in the interval.

Work Done.—The total number of patients treated was 4,010, of whom 400 remained from the previous year, the average daily sick 392·02 and the percentage of deaths to total treated 20·14, compared with 3,986, 364·59 and 17·76 respectively in 1903. Forty-one patients died within twenty-four hours and eighty within forty-eight hours from the time of admission.

In the female ward twenty-four patients remained in December 1903, and 121 were admitted during the year, making a total of 145.

Table A shows the admissions and deaths from the principal diseases for the past four years. It will be seen that there was a very considerable increase in the number of beri-beri cases, the admissions and deaths being nearly twice as many as in the previous year.

Table B shows the admissions and deaths of different nationalities for beri-beri, together with the rainfall for each month of the year. An inspection of this will show that contrary to the usual rule observed here, there was no increase in the number of cases admitted during the wet autumn months.

Fifty-two lepers were admitted during the year, of whom forty-six were transferred to the Leper Asylum.

TABLE A.

Table showing Admissions and Deaths from the Principal Diseases for the past Four Years at the Pauper Hospital, Penang.

Diseases.	1901			1902			1903			1904

PROVINCE WELLESLEY.

Report by Dr. W. H. Fry, Colonial Surgeon.

The estimated population for Province Wellesley for 1904 is 117,762, compared with 117,078 in 1903.

This is computed to be as follows :—

Europeans	186	Malays	69,370
Eurasians	304·5	Indians	19,919
Chinese	26,889·5	Other Nations	1,093

The *births* numbered 3,778, compared with 3,813 in 1903, being 32·08 per mille of population, compared with 32·58 in 1903.

The *deaths* were 3,392, compared with 3,279 in 1903, being 28·79 per mille of population, compared with 28·02 in 1903.

The number of deaths among infants from worms and convulsions continues very high, being no less than 741 from both causes for the entire province; in consequence of this a circular was in September issued to all police-stations and Penghulas detailing the chief symptoms and signs of worms, their causes, and treatment to be adopted. It is possibly in consequence of this that the death-rate from these parasites has in the northern district sunk from an average of 16 to 10 per month, and in the central district from 5 per month to 3 only. I have no doubt, however, that unless the circular is continually brought to notice the benefit will not be permanent.

The number of cases admitted to hospitals throughout the whole province was 1,588, with 208 deaths, compared with 1,469 cases and 241 deaths in 1903; this being a death-rate of 13·09 per cent. of admission to hospital, compared with 16·40 per cent. in 1903.

Zymotic Disease.—Comparatively few cases of small-pox occurred in the province during the year; this was anticipated from the number of cases (258) of this disease in 1903, it having been observed that an unusual number in one year is usually followed by one or two years' remission of the disease.

Some few cases of chicken-pox were reported, chiefly in the neighbourhood of Prai and Butterworth.

Dengue fever occurred throughout the province, but to no great extent, such few cases as sought admission to hospital did so for the rheumatic pains and other sequelæ of the disease.

The cases of small-pox numbered 6 with 2 deaths, and of chicken-pox 7 cases with no deaths.

Of the above, 9 were treated at the General Hospital, Butterworth.

One case of small-pox which afterwards proved fatal was too ill to be removed from his house when first seen. None of the persons affected had been revaccinated since infancy.

The nationalities of those affected comprised 7 Hindus and 6 Malays, 9 being males and 4 females.

General Hospital, Butterworth.

Work Done :—

Remained from 1903	34
Admitted...	479
Discharged	391
Tranferred	6
Absconded	17
Died	55
Remained at end of 1904	44

Of the 55 deaths, 7 occurred within twenty-four hours of admission.

Number of males admitted 426; died 428. Number of females admitted 53; died 7.

Average daily number of sick, males 42·35 and females 3·08.

Percentage of death to total treated was 10·72, or excluding those that died within twenty-four hours, 9·31.

The chief diseases treated comprised :—

Venereal Disease ...	58 with two deaths.
Ulcers	51.
Wounds and Injuries...	42.
Diarrhœa	35 with 15 deaths.
Intermittent Fever ...	21.
Beri-beri	19 with 3 deaths.
Dysentery	9 with 3 deaths.

Operations.—Forty-nine operations were performed, chiefly of a minor nature.

Venereal Disease.—Of those admitted with venereal disease, eighteen stated that they had contracted the disease from Chinese or Japanese prostitutes residing at Campbell or Cintra Streets, Penang. I shall again refer to this subject later on.

Government District Hospital, Bukit Mertajam.

Remained at end of 1904	42

Of the 99 deaths, 17 occurred within twenty-four hours of admission. Average daily number of sick, males 46·82 and females ·80.

The chief diseases treated included :—

Ulcers	99 with one death (from exhaustion).
Venereal Disease ...	79 with three deaths.
Beri-beri	54 with 21 deaths.
Malarial Fever ...	43 with 5 deaths.
Debility	47 with 8 deaths.
Rheumatism	37.
Dysentery and Diarrhœa	34 with 11 deaths.

Province Wellesley, Southern Division.

Report by Dr. A. H. Keun, Colonial Surgeon.

The hospitals in the Southern Division of Province Wellesley are four in number, viz., the Government District Hospital at Sungai Bakap, and the three Estate Hospitals of Batu Kawan, Caledonia and Byram.

The Government District Hospital, Sungai Bakap.

During the year the general wards and outhouses were whitewashed and damar varnished, while the Colonial Surgeon's quarters were re-roofed and various petty repairs executed in all the hospital buildings.

An attempt was made at repairing the Contagious Disease Ward, but owing to the dilapidated condition of the building it was deemed advisable to include a new shed in next year's estimates.

Water supply remains as before, and is from surface wells, the drinking water well being within the hospital grounds, and the well for washing purposes in a Malay Campong within 200 yards of the hospital. The supply continues good and abundant.

Work Done.—On January 1st there were 23 cases under treatment in hospital. The admissions during the year amounted to 504, forming a total of 527 treated. This shows a distinct advance on the previous year, when 342 cases in all were treated. There were 54 deaths, giving a percentage of 10·24. This compares most favourably with the 56 deaths of last year, with its percentage of 16·37 to the total treated. Of these 54 deaths, 4 took place within twenty-four hours. The principal diseases treated were general and local injuries with 74 cases and 3 deaths (2 from exhaustion after severe scalds and 1 from pyæmia in a compound fracture of tibia case). Ulcers came next with 40 cases. As is usual in the province, diarrhœa accounted for a number of admissions, viz., 33, of whom 11 died, making a percentage to total diarrhœa treated of 33·3. This contrasted with the 66·85 per cent. (of deaths from diarrhœa to total diarrhœa treated) of last year shows a distinct improvement. Rheumatism of a subacute nature accounted for 28 admissions with no deaths. Malarial fever 29 (no deaths); anæmia, 30 cases with 7 deaths; debility, 17 cases with 3 deaths; leprosy, 11 cases; acute pneumonia caused 9 admissions with two deaths; and cirrhosis of liver 6 admissions with 2 deaths. From the returns of the Government District Hospital as well as from the returns of the various Estate Hospitals in the South Province, it will be seen that while diarrhœa continues, a factor accounting for large admissions and high mortality, there is on the whole a distinct improvement everywhere. The Tamils are especially susceptible to this disease. The gastro-intestinal canal appears to be the most vulnerable point of a Tamil. Various are the theories to account for the prevalence of the disease in the estates, and the water supply has again and again been held responsible for the disease. It was with the object of removing this source of danger that the Penang Sugar Estates erected water boilers and sterilisers to supply boiled and sterilised water to the coolies in all their estates in the province. In addition sterilisers were put up in the hospitals for hospital use. Boiled water has been in use since April, 1903. As a result this year saw a distinct decrease in the admissions from diarrhœa and dysentery. However, other factors besides the drinking water are responsible for bowel disorders. Among the most prominent I would place the long hours many of the coolies have in the fields exposed to all sorts of weather; the imperfect nutrition which of necessity many of them have owing to their having to cook their own dinners on their return home after 5 p.m. or so, when too exhausted and depressed, many prefer to feast on cakes and other innutritious food and filth sold in the Kuchis; but above all the very chilly evenings and nights play a most important part in filling our hospitals. Many of the coolies have to sleep on the bare ground, sometimes on planks resting directly on the ground. In the early morning there is always a distinct fall in the temperature, and the damp cold ground extracts the heat from the bodies lying over it. This leads to a chilling of the system, which among the Tamils manifests itself by bowel disorders. But the predisposing causes are equally important. In many of the batches that have arrived, the managers state, are weak coolies who are unable to resist intestinal disease and who succumb to the first attack. To attempt to fix on one cause as the chief factor in the causation of this disease is impossible, and in the consideration of the causation of the disease the one fact must always be borne in mind that in the Tropics the bowels are the organs most susceptible to disorders, and such disorders are frequent from injudicious dietary, impure water, chills, exposure, or excessive exhaustion.

Hospital Staff.—I was in charge during the whole year. There was no Assistant Surgeon in the hospital during the whole year; third grade dresser S. Dorasamy did very good work, while Mr. A. Moses ably seconded him.

Batu Kawan Estate.

Under the management of Mr. Lamb, a series of improvements was effected in the hospital buildings and outhouses. New roofing to all the wards (except the Chinese and Middle Wards) and new bertam sides were fixed. Improvements were also effected in the coolie lines. A few lines were rebuilt and an innovation of distinct value, viz., raised platforms for beds, &c., made. On September 18th, a gang of scavengers was organised to attend to the scavenging of the lines. Previous to this date the work was done by the general body of the coolies on Sundays. The estate employs free and indentured coolies, the latter include Tamils, Japanese and Chinese, each living in their own special lines at a distance from each other.

The strength of the working element is as follows:—

Indian Immigrants and Second Contract Coolies	162
Free Tamil Coolies	252
Javanese Coolies	52
Tamil Kongsi Coolies	350
Chinese	70
Total ...	886

The *water supply* continues the same as previous years, and was ample during the whole year. For the convenience of field workers fresh water is conveyed in boats daily to the fields for drinking purposes.

Hospital Staff.—Mr. Thomas continued as dresser in charge and his work generally was excellent. At present he has no assistant under him.

Tamil Patients.—On January 1st there were 14 Tamil patients. There were 239 admissions, making a total of 253 cases treated. There were only 3 deaths, one from tetanus, one from diarrhœa, and one from child-birth. Mortality, 1·18 per cent.

Chinese Patients.—On January 1st there were 5 Chinese patients. There were 36 admissions, making a total of 41. No deaths occurred among them in hospital.

Colonial Medical Reports.—No. 21.—The Straits Settlements *(continued)*.

Javanese Coolies.—The year only saw 17 admissions with no deaths. Among the Tamils ulcer was the prevailing disease, 88 cases; febricula came next, 55 cases with no deaths; diarrhœa next, 28 cases with one death; chicken-pox, 14 cases no deaths; gonorrhœa, 10 cases.

Among the Chinese diarrhœa came first, 6 cases with no deaths; ulcers, 6 cases; anæmia, 4 cases no deaths; and among the Javanese coolies rheumatic pains accounted for 4 admissions, and diarrhœa for 3.

In studying the diseases occurring among the different nationalities, it is interesting to note that diarrhœa is prevalent among them all, though more so among the Tamils. That the Chinese should suffer shows that the water cannot be the only cause, as Chinese scarcely ever drink cold water. Hot water and hot weak tea are their universal drinks, even on the estates. The decline in the mortality of diarrhœa is well shown in the following table of mortality.

	1901		1902		1903		1904		
	Tamil	Chinese	Tamil	Chinese	Tamil	Chinese	Tamil	Chinese	Javanese
Diarrhœa	149	..	111	6	63	16	28	6	3
Death Percentage..	20·80		16·23		6·32		3·57		

Caledonia Estate Hospital.

Various repairs were executed in the hospital buildings, but of a petty nature. The drainage of the hospital remains the same.

Water Supply.—Last year the boiling apparatus erected in Caledonia was completed, and this has since been in use during the whole year; about 9,000 gallons of water a day are boiled, and this water is conveyed in pipes to both the Caledonia and Victoria Kuchis, where it is stored in iron cisterns. These cisterns are cleaned about twice a month. Water is to be found in them at all hours of the day and night, ample in quantity for all the coolie uses. A few standpipes on the roadside gave a liberal supply. While the water supply is ample for all purposes, one cistern and one outlet or tap only for each Kuchi are wholly inadequate. The hospital steriliser is also in use for hospital purposes. There was a temporary stoppage from October to November, owing to leakages. The water used is obtained from the Jawi stream before it reaches the coolie lines.

Hospital Statistics.—During the year, 1,508 cases were treated in the hospitals, with 46 deaths, giving a percentage of 3·05. This contrasted with the 1,433 cases treated in 1903, with 75 deaths (5·23 per cent.), shows a distinct improvement in the mortality of the estate. The admissions to this estate hospital are chiefly from Victoria and Caledonia Estates, while Krian Brick Fields have supplied three patients. It is interesting to contrast the various admissions with reference to nationalities, and the mortality of the separate estates. It is at once seen that Victoria Estate has supplied the largest number of Tamil patients and the highest mortality. This is accounted for by that estate receiving most of the newly arrived indentured coolies, and it is among such men, who arrive debilitated after their sea-voyage, and are put at once on field duty, unaccustomed to the climate and perhaps to the food, that gastro-intestinal diseases, which perhaps accounted for most admissions, do most mischief.

	Diarrhœa	Deaths	Dysentery	Deaths
Victoria Tamils..	145	6	53	6
Caledonia Tamils	44	1	20	3
Javanese.. ..	23	..	4	1
Bengalis	5	..	1	..
Total ..	217	7	78	10

In 1903, diarrhœa and dysentery, for both estates, accounted for 356 admissions, with 41 deaths (11·5 per cent.). In 1904, the total admissions for diarrhœa and dysentery were 295, with 17 deaths, giving a percentage of 5·7. This speaks in itself of the distinct improvement in the health of the estates, and shows that diarrhœa and dysentery are not the formidable diseases they used to be. Of these admissions for diarrhœa and dysentery, 118 cases came from Victoria, with 12 deaths, and 64 from Caledonia, with 4 deaths, the percentage of mortality being practically the same in the two estates (a little over 6 per cent.). The other diseases treated were local and general injuries, 263 cases; intermittent fever, 136; simple continued fever, 65; gonorrhœa, 84; ulcers, 44; bronchitis, 39.

Hospital Staff.—Dr. Ellery, the Estate Medical Officer, was in charge during the whole year. The staff remains the same as in the previous year, viz., two experienced dressers, one apprentice dresser, and a number of attendants.

The Cook-houses, which I referred to in last year's report, did excellent service this year. Every indentured coolie must take his meals here during his first month on the estate; afterwards he may continue at his own pleasure. There is an average of about ninety coolies at the tables. A cup of hot kanji is served out to the indentured coolies every morning before proceeding to the fields, for which a small charge of half a cent or so is made. This is a measure of great value, as otherwise the coolies would have to go out every morning into the cold, chilly air on an empty stomach, or after partaking of cold rice left over from the meal of the night before.

Byram Estate Hospital.

Various petty repairs were done to the hospital buildings. The hospital latrines were improved. A new ward for infectious diseases was erected, and found serviceable in the measles outbreak this year.

Water Supply.—The hospital boiling apparatus was in constant use during the year. A new steriliser to

supply sterilised water to the whole estate was completed and was in use during the year with only a stoppage of a month. As mentioned in my last year's report, the water is brought up in water-boats from the Jawi Canal, near Caledonia.

Work Done.—On January 1st, 1904, there were 33 cases in hospital. During the year there were 690 Tamil admissions, making a total of 720 Tamils treated, and 305 Javanese, 1,025 in all. There were 23 deaths among Tamils, and 5 among Javanese, 28 in all, forming a percentage of 2·73 to the total treated. Last year there were 18 deaths out of 1,038 cases treated (or 1·73 per cent.).

The principal diseases treated were :—

	Tamil.	Deaths.	Javanese.	Death.
Diarrhœa ...	98	7	24	*Nil.*
Dysentery ...	76	7	27	1
Intermittent Fever	141	—	34	—
Bronchitis ...	24	—	1	—
Colic	12	—	7	—
Gonorrhœa ...	39	—	100	—
Ulcers	72	—	20	—
Local and General Injuries ...	51	—	10	—
Confinement ...	13	—	1	—
Chancres ...	23	—	7	—

The chief feature of the returns of the estate is the number of admissions from venereal disease, especially among the Javanese.

This year saw the commencement of Javanese immigrant labour. Four hundred and three coolies (males 222, females 181), arrived in the estate; of these 100 were found suffering from gonorrhœa and 7 from chancres, or 26·5 per cent. of all arrivals. Immediate steps were taken to examine all the arrivals to isolate the infected ones. While there has been a decrease in the admissions from diarrhœa and dysentery the death-rate has slightly increased, thus :—

1903—291 cases of diarrhœa and dysentery with 16 deaths.

1904—225 cases of diarrhœa and dysentery with 15 deaths.

Krian Brick Fields.

The health of the coolies employed here has always been excellent, and this year only saw three admissions into hospital with no deaths.

Public Health.—This year has been practically free of all epidemics except little outbreaks of measles in Byram and Caledonia Estates, and in Batu Kawan.

Small-pox.—Not a single case occurred in the south province. It is, however, of very great importance to consider the vaccination question of the province. At the present time all children born in the district must be vaccinated within three months, failing compliance the parents are fined. But with a partial wandering population as we have in the province, where many natives migrate from place to place in search of work or to turn their hands to various occupations in various districts, children are often carried by their parents into other districts, and so pass out of the notice of the police and the public vaccinator. In this way large numbers escape vaccination. Parents, while they are becoming conscious of the prophylactic action of vaccination and its beneficial effects in modifying cases of small-pox, still look for the most part on vaccination as a painful operation, and so avoid bringing their children up for vaccination. With such a rich soil for the small-pox germ, it is not surprising that when a few cases of small-pox occur the disease soon spreads and too often reaches epidemic proportions, and the mortality is proportionally high. The only remedy appears to me to lie in the hands of the police. The local police should at once communicate with the police of the district where the natives have gone to, and the information should be sent to the superintendent of vaccinations of that district. It would not be a difficult matter for the police to ascertain the districts the parents have gone to, from friends and neighbours, and in this way a great irregularity could be remedied. The subject of revaccination is also of great importance. While outbreaks of infectious diseases everywhere are always serious in an estate where natives are more intimately in contact with each other, outbreaks are of very great importance owing to their rapid spreading and high mortality. Compulsory revaccination is a necessity. New immigrants should be revaccinated prior to leaving their country or on arrival. In this way one source of danger can be obviated. There was a little epidemic of chicken-pox in Batu Kawan, where 14 cases were treated with no deaths. There were 26 cases of measles treated in Caledonia Estate Hospital, all from Victoria Estate. In Byram, 31 cases of measles were isolated and treated, as well as 12 cases of chicken-pox.

Another subject of very great importance to the health of the community is the prevalence of venereal diseases among the natives. Unfortunately, hospital statistics will not emphasise the danger, as natives do not care to come into hospital to be treated for such diseases, which they know are not immediately fatal, while native treatment has apparently some beneficial results on them. Wandering prostitution is, in my opinion, chiefly responsible for this prevalence. Only the Japanese and some Chinese (Macao) prostitutes reside in recognised brothels. There are a very large number of Tamil and Malay prostitutes who wander from village to village, residing a few days only at each place, and shifting from street to street, and so avoid the complaints of their being nuisances being made by neighbours. Most of these women suffer from venereal diseases, and they are the means of spread of these loathsome diseases. Apparently there is no remedy short of special legislation.

The Sanitary Department is doing slow and steady work in the south province with corresponding improvement in the sanitation of the villages.

Appendix D.

MALACCA.

Report by Dr. F. B. Croucher, Colonial Surgeon.

The general health of the Settlement during 1904 was fairly satisfactory. With an estimated population at the end of the year of 98,878, the death-rate was

32·95 per mille against 33·81 per mille last year, and 31·19 per mille in 1902. The deaths in children under one year of age numbered 851, nearly 25 per cent. of the total.

The chief causes of death were returned as:—

Fever	1,307	against	1,405	last year.	
Convulsions	574	,,	735	,,	
Phthisis	168	,,	163	,,	
Intestinal Diseases ...	261	,,	116	,,	
Beri-beri	284	,,	184	,,	
Debility after Fever ...	97		—		
Old Age	274	,,	252	,,	
Pneumonia	49				
Phagedæna	19				

The total number of births during 1904 was 3,380 (males 1,741, females 1,639), compared with an average of 3,579 during the previous ten years. This gives a birth-rate of 34·19 per mille for the year, against an average rate of 38·34 per mille for the previous decade. Six hundred and thirty-five births (males 344, females 291) were registered within municipal limits.

The total number of deaths registered in the Settlement was 3,259 (males 2,042, females 1,217), as against 3,332 (males 2,008, females 1,324) in 1903, giving a death-rate of 32·95 per mille. Of the deaths, 672 occurred within municipal limits with an estimated population of 15,711, and 2,587 in the country districts. This gives a death-rate for the town of 42·77 per mille, and country 31.10 per mille.

The following were given as the chief causes of the deaths within municipal limits:—

Beri-beri ...	100	against	39	in 1903.	
Fever ...	96	,,	182	,,	
Phthisis ...	53	,,	61	,,	
Convulsions ...	75	,,	150	,,	
Diarrhœa ...	91 (chiefly in young children).				
Dysentery, 45, old age 64, pneumonia 26, premature birth, 18.					

The most noticeable feature in these figures is the increase in the number of deaths from beri-beri.

Small-pox.—One hundred cases of small-pox were recorded in the Settlement during the year with 7 deaths. The disease was generally of a very mild type. Fifty-nine cases occurred in persons previously vaccinated.

Dysentery.—Two outbreaks of dysentery of a very severe type occurred, one in Alei, about 5 miles from town, the other at Alor Gajah. Both were due to a shortage of drinking water, following on a period of very dry weather. At Alei, 52 cases were reported with 27 deaths. This mukim lies very low near the coast, and it is said that deep wells cannot be sunk as the water is saltish. The water for drinking is derived chiefly from shallow surface wells which are easily infected. Dresser Hosie was stationed at Kandang during the outbreak and did his best to aid the people, but I do not think they were ever convinced that the disease was due to the defective water supply. At Alor Gajah there were 27 cases reported with 8 deaths.

There was also a large increase in the number of patients suffering from beri-beri, the admissions being 437, as against 251 cases in 1903. The number of deaths from the disease was 89, against 64 last year.

The other principal diseases treated were malaria, 296 with 5 deaths; rheumatism, 174; diarrhœa, 85 with 24 deaths; dysentery, 74 with 31 deaths; phthisis, 61 with 28 deaths: phagedæna, 49 with 20 deaths; pneumonia, 26 with 15 deaths; syphilis, 85 with 2 deaths; injuries, 99 with one death; nephritis, 24 with 6 deaths; ulcers, 737.

Eighteen prostitutes suffering from venereal disease were admitted during the year.

Operations.—Sixty-nine operations were performed with 4 deaths (amputation of thigh, amputation of leg, resection of intestine for strangulated hernia, and gastrostomy for stricture of œsophagus).

Necropsies.—Ninety-four were made during the year.

Gaol Hospital.

The general health of the prisoners, with the exception of an outbreak of dysentery in October, was satisfactory. The average daily number of prisoners was civil, 5·54, and criminal, 46·56.

Buildings, &c.—The wells were closed early in the year and water from the Ayer Keroh Reservoir laid on. Ventilators were fixed in the lower part of all the cell doors.

Patients in Hospital:—

Remained	*Nil*
Admitted	30
Discharged	24
Died	6
Transferred	*Nil*
Remaining end of the year	*Nil*

Thirty-seven prisoners suffering from beri-beri who had been sent from Singapore in 1903, were still remaining at the beginning of the year. Of these, 3 died, 3 were discharged, and the remainder, much improved in health, were sent back to Singapore. Twenty-nine more were sent here in October. Of these, 2 died, 4 were discharged, and 23 remained at the end of the year.

There was an outbreak of dysentery in October affecting ten of the prisoners, the dresser in charge, and one of the warders. The first case attacked succumbed after two days' illness, and at the *post-mortem* examination there was found extensive gangrene of the large intestine. All the other cases did well with the exception of the warder, who was treated at his own home and died after about four weeks' illness.

The origin of the outbreak remained a mystery; it could not with any likelihood be put down to the water or food supply or to defective sanitary arrangements. Dust is given as one of the means by which dysentery was conveyed. Shortly before the outbreak, owing to the collapse of one of the buildings, excavations were made in the prison yard, and a large amount of sand and subsoil water was thrown up on to the surface. If any dysenteric pronouncing organisms were included it is possible that this was the way in which the disease was produced.

Estimated Population for the Year 1905.—The population during 1905 numbered—52 Europeans, 300,000 Africans, 200 Indians, 100 mixed and coloured persons. Except from an increase of 3 Europeans the number of people was the same as that for 1904.

The population at the present time is probably nearly stationary, as the outbreak of small-pox in 1904-5 and the emigration decrease are compensated for by the birth-rate. An estimation of the birth-rate as regards the coast towns shows this to be 10 per cent. among the married women. No figures are obtainable for the more remote portions of the country inland.

Death-rate.—No records on this are available.

Prevalence of the Disease at Different Seasons.—The table of statistics as regards the prevalence of the disease at the different seasons is apt to mislead, unless it is kept in mind that practically the entire native population emigrates into the interior during the extreme heat of the summer, leaving only those who are in fixed employment on the coast. The population able to present themselves at the hospitals thus varies from 20 to 30,000 during the winter, to 3 to 4,000 during the summer, and of this latter number the patients are confined to those drawn from the adult and more physically strong of the population.

Colonial Medical Reports.—No. 22.—Somaliland Protectorate (*continued*).

As regards the periods when sickness most generally prevails the spring and autumn are the more trying to the Somali natives. This is accounted for by the lack of provision for any variations in the temperature as regards clothing. The native dress remains the same at all seasons, and is of cotton only, while a blanket for use at night is not a common possession.

Among the Europeans resident in the country one observes that definite organic disease is uncommon, and except for the milder types of malarial fever and diarrhœa their diseases are entirely confined to the neurasthenic type, predisposed to by the physical conditions imposed on them by residence in such a hot climate.

In character the diseases of the country generally are not of an aggravated type, though undoubtedly the neurasthenic class of patients require invaliding in many cases before recovery takes place.

Relative Mortality at the Different Seasons.—January, February, and March are the months in which most sickness prevails, closely corresponding to the rainy season of the year as regards the coast.

Causes Affecting Public Health.—Meteorological: The hot, violent sandstorms which continue during the summer do undoubtedly lower the physical condition of both Europeans and natives alike. These hot winds seem to be responsible for most of the anæmic and debility cases. As regards other causes at work besides the meteorological, the general health is affected by the almost absolute absence of fresh vegetables among almost all classes over the greater part of the year. The natives do not cultivate, but live on camel's milk and meat, and occasionally on mutton. Camel's milk is also the chief source of salts in their food.

The poor Somali lives, therefore, very much, as regards his diet, on a par with some of the South American tribes, whose diet is almost exclusively animal, except for matté, a plant allied to and used as tea. Certainly directly the Somali is deprived of camel's milk he very quickly develops scorbutic symptoms. The natives as a race are total abstainers from alcohol, a very considerable asset as regards their physical condition.

Remarks on the Particular Diseases which have occurred during the Year.—Dysentery: All the cases which have come under my personal notice have been of an exceptionally mild type.

Malarial Fever.—The hospital figures show remittent fever on the coast to be exceptional. Of the different towns, Berbera is the one most affected by intermittent fever, probably due directly to the sufficiency of fresh water allowing a surface drainage and breeding ground for mosquitoes on the foreshore of the harbour. Mosquitoes seem to entirely disappear during the very hot months—that is, from May to October. Except for imported cases the towns of Bulhar and Zeyla are almost entirely free from malaria the whole of the year, due to the scarcity and expense of water leading to care and prevention of waste.

Insanity.—Cases of insanity of any of the recognised types are almost unknown, and but for syphilis most of the predisposing causes are absent. Cases of monomania, of which a few exist, do not readily become subjects for treatment at the protectorate hospitals.

Diseases of the Skin.—The large number of skin diseases recorded are accounted for under ulcers chiefly, these ulcers being on the legs and ankles of badly nourished subjects, and are of the usual tropical type.

A curious dermatological phenomenon is presented among those of the European population who are for any length of time resident in the country; namely, a redness or hyperæmia, which remains constant, and almost amounts to a staining of darkish red colour, over the *hypothenar palmar* surface of both hands. The condition was first brought to my notice by Mr. H. E. S. Cordeaux, C.B., who has had several years' residence in the country. No actual swelling or other symptoms seem to be related to this condition.

Poisons.—Except in one case, where a vegetable poison was taken by a native as a purgative, which caused death, with symptoms of acute gastric and renal irritation, no cases have occurred except bites or stings of insects.

General Sanitary Condition of the Protectorate.—Probably few other countries have so great a natural protection for the preservation of the public health as exist here. The dry heat and lack of thick vegetation, with the fierce sand storms which sweep the country, dry and cover up any animal or vegetable refuse very much in the same way as occurs in the desert proper. Drainage as such practically does not exist, nor in the ordinary sense is it necessary where the dry earth system exists naturally in so high a degree of perfection.

As regards water supply, only one town, that is, Berbera, can be said to have a moderately good supply service. The water comes from springs at a temperature on leaving the rock of about 100° F., and contains an excess of chlorides, but it is not unwholesome after standing for twenty-four hours to cool and deposit its sediment.

The other towns of Bulhar and Zeyla are supplied from very indifferent brackish wells, mostly situated at a distance from the actual vicinity of the dwellings.

Inland, water of a very fair quality is obtainable in small qualities.

Overcrowding.—This does not exist, as the population is a nomadic one, travelling over its tribal area and living under mat or grass shelters only.

Vaccinations.—The number of vaccinations performed during the year was 1,650; of these, 496 were successful, while in the case of 804 the result was unknown, leaving 350 as unsuccessful in result. It is probable that at the present time about 20 per cent. of the population has been vaccinated; about 5 per cent. of the tribes in the more immediate vicinity to our stations, and with whom we come more directly in contact, have the marks of small-pox.

General Observations.—An attempt has been made to give such demonstrations and instruction in General Hygiene as has come within the scope of interest of the more highly educated native teachers and other residents. Native masons, carpenters and artisans have been approached on matters dealing

more especially with their respective work, in its relationship to the public health.

Ventilation and such like matters in regard to stone-built houses, and the dangers associated with faulty drainage and water contamination have been fully dealt with.

There can be no question as to the fact that phthisis does occur in the country, and I am of opinion that this disease is slowly extending. An isolation hospital is in course of being built expressly for these cases, in the neighbourhood of Berbera.

At the present time a collection is being made of the stinging flies throughout the area accessible to Europeans; this it is hoped may prove a practically complete one when forwarded to the British Museum, for whom the collection is being made.

There have been no cases recorded of any disease deserving special mention, or report.

Colonial Medical Reports.—No. 23.—Gambia.

MEDICAL REPORT FOR THE YEAR 1905.

PATIENTS IN HOSPITAL.

	Remaining in Hospital Dec. 31st, 1904	Admitted during the Year	Died	Remaining in Hospital Dec. 31st, 1905
Europeans ..	Nil	17	2	Nil
Natives ..	16	436	27	18
Civil Force ..	1	45	2	2
Syrians ..	Nil	29	2	Nil
W. A. F. F. ..	7	79	1	4
Total ..	24	606	34	24

The deaths were due to the following diseases:—Beri-beri 1, blackwater fever 1, bronchial asthma 1, broncho-pneumonia 1, burn 1, acute gastritis 1, chronic pyæmia 1, chronic peritonitis 1, cardiac disease 2, chronic bronchitis 2, cerebral congestion 1, dysentery 1, debility 2, hospital gangrene 1, malignant fever with hyperpyrexia 1, meningitis 1, marasmus 1, phthisis 1, phagadoena 1, inanition 1, pneumonia 1, rheumatic fever 1, sleeping sickness 2, senile decay 2, starvation 2, tetanus 2, renal disease 1, acute bronchitis, 1.

The prevailing diseases were the following:—Intermittent fever, remittent fever, conjunctivitis, catarrh, dyspepsia, orchitis, œdema, whitlow, febricula, rheumatism, bronchitis, pneumonia, diarrhœa, abscess, ulcers, boils.

Of the rarer diseases met with there were guinea worm, syphillis, sleeping sickness, gout, leprosy, beri-beri, tetanus.

The following table shows the number of cases of illness and invalidings among Europeans during the past five years and the number resident in the colony for each year.

Europeans	1901	1902	1903	1904	1905
Number of Residents ..	88	98	105	100	114
Treated	89	26	47	42	43
Died	4	2	2	Nil	1
Invalided	3	2	2	Nil	1
Malarial Fever Cases ..	54	11	15	24	16
Blackwater Fever	..	..	..	..	6

The diseases suffered from were the following:—Biliousness, cellulitis, pleurisy, ulcer, febricula, and remittent fever.

Years	Total Deaths	Rate per 1,000	Deaths under 5 Years	Rate per 1,000
1901	340	38·63	137	15·56
1902	266	30·22	112	12·72
1903	315	35·79	130	14·77
1904	303	34·40	124	14·07
1905	299	33·95	117	13·29

The statistics of population for the year 1905 are:—Europeans 114, Africans 8,807; Increase 14 Europeans.

There has been no structural building or alteration during the year.

The European Staff remains the same.

The tank supply of water has been ample, although the two largest tanks are leaking.

Expenditure.

Salaries and Allowance ...	2,427	0	9
Drugs and Maintenance ...	561	10	7
	£2,988	11	4

Among the 35 European officials there has been no serious illness.

The following diseases are recorded :—remittent fever 11, cellulitis 1, pleurisy 3, biliousness 1, febricula 3. Accidents : dislocated shoulder 1, injury to foot 1, strain 1.

Of the non-official Europeans one was invalided to Europe for persistent anæmia following fever.

Other cases were :—fever 16, anæmia 1, nephritis 1, catarrh 1, blackwater 3, biliousness 1, abscess 2 ; also some slight wounds.

There has been great improvement in the health of the prisoners in the Bathurst Goal. Only one case of beri-beri occurred, and this was undergoing punishment before the improvements were carried out (1903).

The prisoners are now more than ever employed outside the gaol, and also they are available for work on the new Victoria Recreation Ground (late McCarthy Square). This has had much to do with their good health.

The water supply is the same as before and has been ample.

Fortnightly meetings of the Board of Health took place regularly. Thirty labourers in the rains and twenty at other times are continually employed in sweeping and scavenging the town. Three carts and three horses are in constant use. These carts removed 4,780 loads of refuse, &c., also 311 loads of tins, bottles, &c.

There were 91 " Abatement of Nuisance " notices served, also 4,790 house-to-house visits, but no summonses nor convictions. Thirty labourers were employed.

Vaccinations were carried out regularly ; 987 vaccinated, of which 968 were successful. This is more than double the number of the preceding year, and ·01 unsuccessful only. Practically all were children or young adults. The same lymph as used the year before has proved very successful.

The efforts at vaccination in the Protectorate have been met with no response or appreciation by the natives.

The name of " McCarthy Square " is now altered to that of " Victoria Recreation Ground." During the rains of the year (1905) the square was enclosed with an iron railing. Gates were placed in the centre of each side. A macadam path near the railing is being carried round the Square and shrubs and plants in tubs are being planted. Eighteen garden seats (to hold four each) have also been provided ; also a lawn mower.

Jubilee Hospital Fund.

Dr. Total Receipts	£801	3	3
Cr. Total Expended	469	5	11
Balance Transferred to McCarthy Square Management Fund	331	17	4

Signed F. A. Baldwin,
Acting Senior Medical Officer,
February 28th, 1906.

In response to an official request Dr. Hopkinson states :—Although I am afraid that the above remark still holds good for the greater part of the Protectorate, there is at least one district (Kwinella and neighbourhood) where vaccination is really appreciated, and where genuine disappointment has been shown when I have visited that part without enough lymph to vaccinate all who apply. Again this year in the Upper River I found the same attitude. In other parts, however, hitherto my only vaccinations have been done when with His Excellency, his support and countenance having great weight with the people.

In response to an official request concerning the number of children vaccinated Dr. Hopkinson replied : —In 1905, 226 children were vaccinated by me in the Protectorate—in the McCarthy Island and Upper River Districts ; and 265 by Dr. Franklin in the South Bank and Kommbo. Total for 1905, 491. In 1906 I have vaccinated 85 at Willingharra and Kwinella. Total for 1905-6 up to date, 576.

In several places, notably Kwinella, Batelling and in Dembo Danso's District in the Upper River, I could have done at least twice as many vaccinations had lymph been available.

Colonial Medical Reports.—No. 24.—Southern Nigeria.

MEDICAL REPORT FOR THE YEAR 1905.

European Medical Staff.

The medical staff consists of 35 medical officers and 7 nursing sisters. During 1905 one medical officer was permanently invalided, another was murdered, and the Principal Medical Officer retired on a pension.

Health.

The health of the Europeans throughout the Protectorate has been fairly satisfactory.

European Population.

The average European population was 533, viz., 494 males and 39 females.

European Death-rate.

There were 12 deaths during the year, viz., 5 officials and 7 non-officials. In addition, 3 officials and 3 non-officials died a short time after their arrival in England of diseases contracted in the Protectorate. The death-rate calculated on those who died in the Protectorate is at the rate of 22·5 per thousand, or including the 6 that died in England, 33·7 per thousand.

When comparing the death-rate with that of England, it is well to note that there are no deaths in infancy or from old age.

Causes of Death.

Of the 12 deaths that occurred in the Protectorate, 7 were due to blackwater fever, 1 to malarial fever, 1 to cardiac failure in gastritis, 1 to apoplexy, 1 to accidental drowning, and 1 was murdered by the natives.

Invalidings.

Forty-three European officials and 45 non-officials were invalided.

Of the 43 officials 6 were permanently invalided out of the service, and another died within a short time of his arrival in England. Of the 88 invalided, 50 returned to Europe and 38 were sent for a sea trip. This gives an invaliding rate of 150 per thousand. Undoubtedly a high percentage, but probably the means of reducing the death-rate, which compares favourably with previous years.

Death-rate and Invalidings Compared with those of 1904.

In 1904 the average resident European population was 500, deaths 19 (including 2 in England), invalidings 42.

In 1905 the population was increased by 33, the deaths, including the 6 that died in England, are 1 less than in 1904, and the invalidings show an increase of 46 over those of 1904.

Prevalent Diseases.

Europeans suffered principally from malaria and disorders of the digestive system. The disorders of the digestive system were, as a rule, functional. A large percentage of Europeans suffered from some form of dyspepsia. This, in my opinion, is due to one of the following causes: (1) General deterioration in health; (2) bad cooking; (3) inappropriate foods. It frequently happens that a person when he first begins to suffer from dyspepsia considers it trivial and not necessary to consult a doctor about, and it is not till the complaint has become more or less chronic that he seeks the advice of a medical man.

Filarial Infection.

I regret to say I came across two fresh cases of filarial infection amongst the Europeans. These filariæ are about $\frac{1}{90}$th of an inch in length, and millions are, as a rule, present in the circulation. A large number of natives suffer from filariæ, and it is from them or from the infected European that the mosquito becomes infected, and he in his turn infects the European. All resident Europeans are now aware, I presume, of the mosquito theory of malaria, and a large number also know of the mosquito theory of filariæ, yet in spite of this you find Europeans who do not consider it necessary to use a mosquito curtain in districts where the mosquitoes though present are not sufficiently numerous to be troublesome. The question arises as to what is to be done with a European infected with filariæ. I am of opinion that he should not be allowed to remain in a place where there is a European reservation.

Quinine.

There appears to be a growing tendency amongst some European residents to underrate the value of quinine as a prophylactic against malaria. They become imbued with the idea that certain ailments, such as loss of memory, neuritis, dyspepsia, blackwater fever, are caused by its use. This idea is, to a certain extent, fostered by some medical men in England occasionally attributing a West African's ill-health to the taking of too much quinine.

After many years of experience, I am of opinion that the above-mentioned ailments are much more likely to be caused by malarial infection than by the use of quinine as a prophylactic, and those, particularly the more recent arrivals, who neglect to take quinine as a prophylactic because of its possibly causing loss of memory, &c., are not acting with justice to themselves or their employers.

Calabar (Europeans).

The health of Calabar as regards serious illnesses was good, though there was an increase in the number of those treated for slighter ailments. Many of the residents now realise the fact that a very narrow margin separates the slight fever from the malignant one, the former being as a rule a milder type of the latter, and they send at once for a medical man when they become ill, instead of waiting to see what will happen.

European Hospital.

I cannot speak too highly of the value of the European hospital to the residents, nor of the great assistance the nursing staff under Miss Graham is to the medical officers.

A patient who is at all seriously ill is attended day and night by one of the European sisters, and it is to that as much as anything else that I attribute our successful treatment of hospital patients. I strongly recommend such a system to those hospitals in West Africa where European nurses are not employed on night duty.

Cases Admitted to European Hospital.

One hundred and seventy cases were admitted during the year, with 2 deaths. Of the 2 deaths 1 died of blackwater fever, and the other had been brought from the Cross River suffering from malignant malaria. He was in a moribund condition on admission, and died within a few hours.

Calabar Gaol.

The health of the prisoners during the first six months of the year was bad, and the death-rate high. The majority of the deaths occurred amongst those who were old and decrepit. A type of dysentery, which, with few exceptions, was invariably fatal when it attacked those past middle age was responsible for a large number of the deaths. All known forms of treatment and the best possible nourishment appears to be of little or no use in these cases. The growing adult does well in prison, and as a rule puts on weight. The health of the prisoners during the second six months of the year was good.

Lunatic Asylum.

The asylum is at present only used for criminal lunatics. Accommodation is provided for the lunatics in three mud and wattle houses. Each house contains 4 rooms. In addition, there are 3 isolation wards made of cement blocks. I am of opinion that more permanent buildings than the present mud and wattle ones should be provided, and that a wall instead of the present wire fence should separate the males from the females.

St. Margaret's Native Hospital, Calabar.

There were remaining from 1904, 42 cases, and 767 were admitted, making a total of 809 intern patients treated. Thirty-nine deaths occurred amongst those treated. Twenty-two major operations were performed, with 3 deaths.

Major Operations Performed, 1905.

	No.	Result	
		Successful	Died
Amputation of Limbs	4	4	—
Excision of Breast	1	1	—
Excision of Tumours	3	3	—
Craniotomy	1	—	1
Elephantiasis	4	4	—
Radical Cure of Hernia	6	5	1
Hernia (Strangulated)	1	—	1
Hip-joint	1	1	—
Plastic	1	1	—
	22	19	3

The case of strangulated hernia was virtually moribund when operated upon. In addition to the above, I operated successfully on a European with *supra-hepatic abscess*.

The two Roman Catholic Sisters are doing good work at the native hospital. Their principal duty at present is to attend to female patients and to assist the medical officer in his gynæcological work.

Extern Patients.

Seven thousand six hundred and eighty-two extern patients were treated. I attach a table of cases treated.

Water Supply.

The water continues to maintain its high standard of quality, and is practically unlimited. I attach analysis of same. The water has been laid on to the various trading factories, and for the future they will be able to use this water instead of rain as heretofore.

Small-pox.

I am pleased to be able to report that no case of small-pox occurred in the Calabar district. A new contagious diseases hospital has been built, and will be open to patients next year.

Vaccination.

Twenty-four thousand and seventy-nine successful vaccinations are reported as having been performed throughout the Protectorate.

Meteorological Returns.

(All temperatures are recorded in degrees Fahrenheit.)

At Calabar the maximum shade temperature recorded was 92·71, and the minimum 70·67. The former was in February and the latter in August. The highest monthly mean temperature was 84·37 in March, and the lowest 77·15 in August. The mean temperature for the year being 81·21. The total rainfall was 167·39 inches. The mean degree of humidity, 84·29.

Bonny.

The maximum shade temperature was 96·21 recorded in February, and the minimum shade temperature 62·13, also in February. The highest mean monthly temperature was in March, viz., 81·66, and the lowest 76·63 in August. The mean temperature for the year was 79·58. The total rainfall was 167·75 inches. The mean degree of humidity, 83·78.

Sapele.

The maximum shade temperature was 90·32 recorded in February, and the minimum 70·42, also in February. The highest monthly mean temperature was 79·97 in March, and the lowest 75·15 in August; the mean temperature for the year being 77·86. The total rainfall was 116·25 inches. The mean degree of humidity, 84·55.

Asaba.

The maximum shade temperature was 96·19 recorded in March, and the minimum 67·83 in December. The highest mean monthly temperature was 80·88 in March, and the lowest, 75·79 in July. The mean temperature for the year was 77·89. The total rainfall, 59·42 inches. The mean degree of humidity, 81·88.

Bende.

The maximum shade temperature was 91·29 recorded in March, and the minimum 67·87 in December. The highest mean monthly temperature was 80·29 in March, and the lowest, 74·87 in August. The mean temperature for the year was 77·21. The total rainfall, 74·67 inches. The mean degree of humidity, 82·12.

Owerri.

Returns only made out from April to November. Rainfall, 92 inches. Maximum shade temperature, 91·57 in April. Minimum shade temperature, 71·25 in August.

Forcados.

Returns only made out from July to December. Rainfall, 87·81 inches. Mean degree of humidity, 86·44. Maximum shade temperature, 87·61, recorded in December. Minimum shade temperature, 72·48 in July.

Onithsa Plantation.

The maximum shade temperature was 92·83 recorded in April, and the minimum shade temperature 72·16 in January. The highest mean monthly temperature was 81·61 in March, and the lowest, 75·73 in July. The mean temperature for the year was 78·73. The total rainfall, 60·07 inches. The mean degree of humidity, 79·01.

Benin City.

No returns were furnished for March, April, and May. The maximum shade temperature was 88·71 recorded in February, and the minimum shade, 67·83 in December. The highest mean monthly temperature was 79·83 in June, and the lowest 74·71 in August. The mean recorded temperature for the year, 77·22. Recorded rainfall, 138·75 inches. Mean degree of humidity, 83·02.

Afikpo.

The maximum shade temperature was 91·70 recorded in April, and the minimum shade temperature, 69·22 in December. The mean monthly temperature was 82·69 in March, and the lowest, 76·87 in September. The mean temperature for the year was 79·00. The total rainfall, 83·88 inches. The mean degree of humidity, 82·66.

Calabar Town.

The sanitary condition is much improved. Roads and drains are being made throughout the town. Four latrines have been built, and are of great convenience to the natives. I think another four might with advantage be erected. The town is growing rapidly. I am of opinion that this growth is due to aliens from Lagos, Gold Coast, and Sierra Leone, rather than to the aborigines of the place.

The removal of the soldiers, with their wives and families, to the new barracks will be an important step towards European reservations. Owing to the large percentage of children that harbour the malarial parasites, they are undoubtedly a source of great danger to Europeans.

The sick returns throughout the Protectorate have heretofore not been made out in accordance with the "model return," so regret that, with the exception of Calabar, I am not in a position to furnish the model return for out-stations.

Bonny.

The health of both Europeans and natives was good. At present the medical officer has only one room in which to store his medicines, dispense and attend to patients. In the native hospital which is being built proper accommodation in the form of a consulting-room, dispensary and storeroom are provided. One of the stores at Tunnicliffe House has been fitted up as a prison. This store is well ventilated, and the floor has been raised, and as a lock-up is most suitable. Excluding the cases of beri-beri sent on from Calabar only four cases requiring to be isolated occurred in Bonny during last twelve months, two having been landed from a steamer. The health of the children at the Government school has been very good, and the water supply excellent.

European deaths, *nil*. Invalidings, *nil*.

Egwanga.

The health during 1905 was good. The native hospital is a very good type of native hospital. At one end there is a consulting-room, dispensary and storeroom, and at the other end quarters are provided for the native dispenser. The natives are now beginning to appreciate the advantages of such a hospital. The medical officer has done what he can to improve the sanitary condition of Opobo town, but owing to its low-lying situation and swampy condition little can be done in this direction. Much good work

has been done by carrying out the vaccination scheme, and small-pox, which was once very prevalent, is but seldom met with. The native town of Egwanga, which was a hotbed of disease, and was in close proximity to the European residences, has been cleared away.

Deaths amongst Europeans, *nil.* Invalidings, 7.

Degama.

All Europeans now live on the beach, and the hulk *George Shotton*, which was for a number of years used as a residence for European officials, has been done away with.

A native hospital, with consulting-room, store, and dispensary is being built. When completed this will be of great assistance to the medical officer, who up to now has had to put up with the most limited accommodation. The health of the prisoners has been fairly good. There was an outbreak of dysentery amongst them which caused several deaths. No cause for this outbreak could be found. The native town of Abonema still maintains its reputation of being one of the cleanest and best kept towns in the Protectorate. Vaccination is still largely carried on, with the result that a case of small-pox is but rarely met with.

Deaths amongst Europeans, *nil.* Invalidings, 8.

Brass.

The health of this station has been good. Though £400 had been allowed in the Estimates, 1905-1906, for a native hospital, it has not yet been built, though I am given to understand that building operations will shortly commence. Up to September the only accommodation the medical officer had, to see his patients in and dispense from, was a room 6 feet by 12 feet. In September Mr. James, who was acting as Deputy High Commissioner, handed over to the medical officer a native house to be used as a hospital and dispensary until such time as the native hospital was built. The health of the residents, both European and native, was good.

Deaths amongst Europeans, *nil.* Invalidings, 2.

Akassa.

The health amongst the Government officials, both European and native, was satisfactory. Two rooms are occupied by the medical officer in the Rest House, one of which he uses as a dispensary and the other as a storeroom. There is no accommodation for sick Europeans or natives. I think it would be advantageous if the dispensary and storeroom were placed on the ground floor, and two rooms were fitted up for sick Europeans. The drainage system between the Marine and Engineer's beach has been most successful, but I think some of the swamp in the immediate vicinity of Marine beach might, with advantage, be filled in.

There is a covered-in well between the Marine and Engineer's beach. I consider this type of well most suitable for out here.

Deaths amongst Europeans, 1. Invalidings, 9.

Onitsha.

This station is rapidly developing, and the headquarters of central division, which were originally at Asaba, have been transferred there. Within a short time Onitsha will have both a European and native hospital. Up to now the medical officer has been placed at a disadvantage in not having such hospitals. The drinking water is stored rain-water. I believe the Director of Public Works has under consideration a scheme for supplying water from a stream in the vicinity. I was able, in August, to station a second medical officer at Asaba and Onitsha. The exigencies of the services in January necessitated my leaving Asaba and Onitsha in charge of one medical officer. I hope to be able to send a second medical officer there shortly.

Deaths amongst Europeans, 3. Invalidings, 8.

Sapele.

The health of the Europeans at this station was good. A result, I have but little doubt, due to the Board of Health that exists here. I would strongly recommend the formation of similar boards at other stations.

With respect to the other stations throughout the Protectorate, I am pleased to report that the various medical officers are most energetic in trying to improve the health of the residents and sanitation of districts.

A. H. Hanley, C.M.G., F.R.C.S.I., &c.,
Acting Principal Medical Officer.

APPENDIX A.

REPORT ON LEPER ASYLUM, ASABA.

The Leper Asylum is a collection of reed huts in which live, on an average, 29 lepers, 13 male and 16 female.

These people, on the whole, seem to lead a happy existence, they are well fed and cared for; they are not enclosed and are practically free to wander where they like.

The admissions during the year numbered seven; a considerable number of lepers demanded admission, which in most cases was refused, owing to lack of funds for their support. Three children were born in the asylum, all of whom died within a short period; four lepers died and three left of their own accord.

In these cases I did not try to prevent their departure whenever satisfied that they were able to support themselves, as, apart from the absence of means of compulsion, I consider the limited accommodation of the settlement could be turned to the best account by being reserved for refugees and prisoners.

The staff consists of one native overseer, who has discharged his duties exceptionally well, and who is extremely gentle to the patients. It appears that the staff is undermanned, and that it is impossible to prevent patients wandering through the markets when they feel inclined during the absence of the overseer.

It is intended that the asylum be removed to Onitsha side in the near future, and, therefore, I do not think it worth while to suggest improvements in the Asaba settlement.

I do not know whether it is the intention of the Government to enforce isolation in cases of leprosy, if so it will be necessary to provide accommodation for at least 1,000 lepers from this district alone, and a scheme which does not embrace all cases is useless. I suggest as the only way of carrying out isolation on a large scale that the villages be required to provide settlements for their lepers, each to be supervised by an overseer appointed by the Government, who, with the headmen, will be responsible that lepers do not wander into the compounds of the healthy; this plan could be tried without expense in one or two of the native court towns and extended if found workable; the settlement at Onitsha could then be reserved for criminals and refugees, of whom there will be a sufficient number to tax its accommodation.

E. MOORE,
District Medical Officer.

Colonial Medical Reports.—No. 25.—Northern Nigeria.

MEDICAL REPORT FOR THE YEAR 1905.

By Dr. S. W. THOMPSTONE.

Principal Medical Officer.

THE average number of Europeans resident in the Protectorate during the year was 342, of whom 277 were officials and 65 non-officials—331 being males and 11 females.

The native population was estimated as being 9,000,000 approximately.

Ten Europeans died during the year, 7 of whom were officials and 3 non-officials.

The total crude European death-rate for the year, calculated on the average resident population, was 29·23 per 1,000. As in former years, there was a very marked difference in the mortality rate of officials and that of other members of the community, there having been 7 deaths among 277 officials and 3 amongst 65 non-officials, giving an official death-rate of 25·27 per 1,000 as against a non-official one of 46·15 per 1,000. The difference is, however, much less marked this year than last, when the rates were 29·62 and 96·15 respectively.

These death-rates are, as stated above, "crude" death-rates, and they are not corrected for age and sex distribution, and are therefore not comparable with that of communities consisting of persons of all ages and both sexes in the proportions met with in Europe.

There has been an increase in the average resident European population as compared with 1904 of 20, last year's population having been estimated at 322. The death-rate has decreased by 11·14 per 1,000, and the invaliding rate by 64·73 per 1,000, the latter rate being 143·27 for the year 1905, as against 208 per 1,000 for 1904.

As in former years, the rainy season has proved the most unhealthy for Europeans, the greatest amount of sickness having occurred during the months of July, August and September. The wettest month, August, was the worst month, and March showed the fewest admissions—the former month having the highest relative humidity and the latter being the driest in the year.

The general character of the diseases prevailing showed little or no change. The case mortality of hæmoglobinuric fever was slightly higher than in 1904, but much lower than in 1903. The figures for the three years being 37·3 per cent. in 1903, 16·1 per cent. in 1904, and 20 per cent. in 1905; the actual number of admissions from this disease being 20, and the number of deaths 4, as against 31 cases with 5 deaths last year.

During the first three months of the year a very severe epidemic of cerebro-spinal fever broke out in all the provinces of the Protectorate—Borgu, Kontagora, Sokoto, and Bornu being the only places that escaped. With the exception of an outbreak among the East African carriers at Cape Coast Castle during the Ashanti Expedition of 1900, this is the first recorded epidemic of this disease in West Africa, though A. Plehn mentions it as being amongst the diseases met with in Kamorun.

From enquiries made among the older natives it would seem that epidemics of this disease occur periodically over the whole of Northern Nigeria, and have been usually even more severe. The tradition is that it came originally from the north-east, but not in the memory of living man. Fifty years ago an epidemic is said to have occurred at Egga on the Niger, and ten years ago Kano was decimated by a very severe outbreak.

It is impossible to estimate the actual number of deaths, but there were certainly over 100 in Bautchi, 250 in Ilorin, and 60 in Zungeru, during the month of February alone, and the natives say that here were 50 deaths a day in Zaria, and 100 a day in Kano during January. Dr. McGahey reported from the Yola district that some of the villages lost 5 per cent. of the population during the three months, that in Yola town itself there were 300 deaths from the disease, and that the case mortality was approximately 50 per cent.

All native accounts agree in its being essentially a dry season disease, which always disappears when the rain begins. January, February and March being the bad months, the dust-storms being probably the cause of its spread, by disseminating the dread nasal secretions containing the causal organisms far and wide. At the commencement of the epidemic the case mortality was appalling—many of those attacked practically falling dead at their work—later, however, its virulence became attenuated and many of the later cases recovered.

Only two Europeans were attacked, both of whom died—one in Kano and one between Zaria and Zungeru; this comparative immunity being almost certainly due to the principle which has been adopted when laying out new stations, of building the European quarters at a distance from the native towns.

Several epidemics of small-pox also occurred during the dry season, but none of any great magnitude. The town of Katagum and an adjacent village called Kudabir suffered somewhat severely, and in the town of Bautchi the Emir stated that there had been 100 deaths during January and February from small-pox. In the Bautchi district it would appear that the disease spread from Kassina, a hamlet south of Zoranda, and from there was carried to Bautchi, and thence spread into the surrounding districts. The village of Keffin Fulani, between Bautchi and Ningwe, was practically emptied owing to the ravages of the disease. With the exception of a soldier and a horse-boy, no cases occurred in the camp.

Colonial Medical Reports.—No. 25.—Northern Nigeria (*continued*).

An interesting fact reported by the medical officer at Bautchi is that the *cow fulani* almost invariably escape small-pox: they are said to practise a form of inoculation of cow-pox virus, having apparently discovered for themselves that the one disease renders them immune from the other. Amongst other natives inoculation with small-pox virus is common—the sufferer being paid a small sum to allow the procedure.

There was practically no difference in the relative mortality amongst the Europeans in the different seasons. There were, however, many more native deaths during the first three months of the year—the increased mortality being principally due to the epidemics of cerebro-spinal fever and small-pox which broke out during the period.

Zungeru.—The rainfall during the year was 41·31 inches, or 9·8 inches less than in 1904; the wettest month being September with 8·04 inches. Rain fell during eight months of the year—March to October inclusive—the heaviest fall recorded being 2·63 inches in the twenty-four hours, on October 15th.

The maximum shade temperature was 106° F., which was recorded on April 8th; the minimum, 56° F., on December 1st. The highest mean temperature for the month was 87° F. in March and April, and the lowest 77·3° F. in August; the mean temperature for the year being 80·1° F. The mean relative humidity for the year was 58, the highest mean being 81·6 for August, and the lowest 33 for January and February—calculated from readings taken at 9 a.m. The lowest actual relative humidity recorded was 16, from hygrometer readings taken at 4 p.m. on April 7th, and December 21st and 30th.

Lokoja.—The total rainfall was 49·64 inches for the year, or 7·92 inches more than last year—the heaviest rainfall occurred in September, 16·28 inches. The maximum shade temperature was 101° F., which was recorded on March 10th, and the minimum 53° F., on December 31st. The highest mean temperature for the month was 87° F. for March and April, and the lowest 78° F. for August and December—the mean temperature for the year being 81° F.

The mean relative humidity for the year was 72, the highest mean being 78·7 for September, and the lowest 60 for March.

The highest temperature recorded in Northern Nigeria during the year was 118° F. at Maifani on April 8th, and the lowest 39° F. at Kano on February 2nd: the highest mean temperature for the year being at Kontagora, 82° F., and the lowest, Zaria, 74° F. The greatest rainfall was at Zaria with 51·27 inches, and the lowest, Sokoto, with 33·32 inches. The maximum fall on one day being at Ilorin, on June 2nd, 4·04 inches.

The general direction of the wind throughout the Protectorate was from the south-west from June to November, and from the north-east during the remaining months of the year, the Harmattan lasting, with slight intermissions, from December to the end of May; the first tornado occurring in March, and the rainy season ending in October.

The meteorological conditions have considerable influence on the health of the community, the dry season being comparatively more favourable to Europeans, owing to the absence of mosquitoes and the more bracing condition of the atmosphere—the nights being cool, and the temperature, though high during the day, owing to the low relative humidity, being much more easily borne than the damp relaxing heat of the rains. The number of admissions from malaria rise rapidly after the first tornadoes, and reach their maximum when the rains are heaviest. The natives, on the contrary, suffer more during the dry season, not only from epidemics, but from respiratory and digestive diseases brought on by the cold nights and scarce and impure water supply.

The greatest amount of sickness during the year among Europeans has been due to malaria. The total number of admissions from this disease (excluding blackwater fever for the sake of convenience) having been 445 with no deaths, compared with 515 admissions with 3 deaths last year.

Twenty cases of hæmoglobinuric fever occurred, with 4 deaths, and 34 of dysentery with no deaths. There were 2 cases of small-pox in Europeans during the year. Among the natives treated there were 1,090 cases of malaria with 12 deaths, 451 cases of dysentery with 48 deaths, and 769 cases of rheumatism with 1 death. Complete lists of all diseases treated both among Europeans and natives are attached at the end of this report.

The general sanitary condition of the European stations is good—the great need being better quarters. The expense of transport of material is so great that in practically all the stations off the rivers officers have to live in mud or grass native-built houses, which harbour insect life and are anything but weatherproof.

The water supplies have been improved where possible, the small condensers supplied to outstations having proved a great success. They have in conjunction with other sanitary measures been the cause of a large reduction in the number of cases of dysentery met with, no death having occurred from this disease during the last two years.

Under the influence of European teaching the large native towns are beginning to show some signs of improvement, but it will be many years before much can be done in this direction.

Zungeru.—The average resident European population during the year was 66—61·6 officials and 4·4 non-officials. The sanitary condition of the cantonment is excellent, the drainage being effective and the water supply good. The series of dams which was constructed last year for the purpose of holding up the water in the Dago and providing for a continuous flow, has answered its purpose admirably, and has now stood the test of two dry seasons.

The drinking water supplied by the condenser is of good quality and sufficient for all requirements.

The general health of the population has been good. The number of admissions to hospital was 92 with 2 deaths, one of which was the case of a patient who was brought into hospital from Barajuko, and whose illness was contracted on the river. Last year there were 123 admissions with 4 deaths—a very marked reduction both in the number of admissions and the case mortality.

Gaol.—The sanitary condition is good, the cells

being kept clean, and the yard dry and well swept. The ventilation works out at about 350 cubic feet per inmate, and as the doors are grated and ample openings are provided in the walls the air in the buildings is always fresh. The water supply is obtained from the Kaduna and Dago Rivers, and is of good quality and ample in amount, no limit being laid down as to the quantity supplied. Combustible refuse is burnt, and excreta carried out in pans and buried in trenches.

The general health of the prisoners during the year has been fair, but many of the inmates were in wretched condition when admitted. The principal diseases which occurred were dysentery, diarrhœa, rheumatism, guinea-worm and pneumonia.

The average number of prisoners was 162; and the quality of the prison diet good.

Freed Slaves' Home.—Both the compound and the buildings are kept clean and in excellent sanitary condition. The average number of inmates during the year was 167, and their general health was good.

Ventilation is free and sufficient, and the water supply, which is obtained from the Kaduna and Dago, is good and ample. All drinking water is boiled before use. The refuse is disposed of by burning and burying in trenches—the pan system for excreta being in use.

The prevalent diseases were stomatitis, diarrhœa, intestinal parasites, and dysentery.

Lokoja.—The average resident European population was 73·8, 60 being officials and 13·8 non-officials. The sanitary condition of the cantonment is very good, great improvement having being effected during the past year. The drainage is satisfactory, and the European compounds and native lines well kept and clean. The drinking water from the condenser has been of excellent quality and sufficient in amount.

The general health of the community has been much better than in any previous year—the admissions to hospital having been only 101, as against 145 in 1904.

Gaol.—The sanitary condition of the gaol is extremely good, and the general health of the prisoners satisfactory. The water supply is obtained from a stream which runs near the prison, and from rain-water tanks on the premises. The supply is ample and the quality good. Ventilation is free and sufficient.

The average number of prisoners during the year was 67; and the prevalent diseases were diarrhœa and malaria.

Kano.—The average resident European population during the year was 21·8. The sanitary condition of the station is as good as circumstances will allow, but drainage is unsatisfactory, as owing to the nature of the ground no proper fall is obtainable at Nassarawa. A new site at Goza has been occupied by the military during the year with a view of testing its suitability for a permanent cantonment, and the results of the year's experience are being submitted separately.

The general health has been unsatisfactory, but so far as can be gathered from the statistics at present to hand, the new site presents distinct advantages over that now occupied by the civil population.

The water supply is derived from wells at Nassarawa, which have proved insufficient for the needs of a large population during the dry season. At Goza it is obtained from pools fed by springs, and has so far proved sufficient.

There were 1,398 successful vaccinations performed during the year, all stations being now supplied with small consignments of lymph by each mail. The greatest difficulty is still experienced in obtaining it in an active condition at those stations which are farthest away from the sea-coast—the results for the year at Sokoto and Katagum being *nil*. In spite of this difficulty considerable progress has been made towards protecting the native troops and the inhabitants of the towns nearer headquarters.

Small-pox is endemic—a very considerable proportion of the adult population showing marks of previous attacks, and those who have not suffered from the disease are becoming keenly alive to the protection afforded by vaccination, being most anxious to have the operation performed whenever an outbreak occurs. To overcome the difficulty of obtaining active lymph the experiment of forming small vaccine stations at two or three stations intermediate in distance from the sea, such as Zaria, Kontagora, and Koffi, would be well worth trying. If these prove a success the system could then be extended with some hope of protecting the population in those portions of the Protectorate in which it has up to now proved impossible to obtain successful results.

Two cases of small-pox have occurred among the European officials, both of which, however, recovered.

The general health of the European community has been better than in any year on record. Both the death-rate and invaliding rate have been much lower than last year, the death-rate, which was 29·23 per 1,000, having been 20·33 per 1,000 less than the average of the previous five years, which works out at 49·56 per 1,000.

STATISTICS OF EUROPEAN POPULATION.

Europeans	1900	1901	1902	1903	1904	1905
Average actually in the Protectorate	165	165	290	309	322	342

the government hospitals and dispensaries during the year was 16,557, an increase of 3,052 over last year. Of these, 1,090 were cases of malarial fever.

Dispensaries have been established during the year in most of the provinces, and although they have necessarily been equipped on a very small scale, 2,531 paupers have been treated throughout the Protectorate during the year.

The permanent enclosures to which I referred in my report last year, which were erected at Lokoja and Zungeru for isolating cases of infectious disease, have been invaluable, grass huts being run up inside them for the accommodation of patients, and burnt when the epidemic subsides. In former years it was found to be practically impossible to prevent the friends of the patients visiting them at night and spreading the disease abroad. This has now been effectually stopped and effective isolation provided.

Venereal diseases are still very prevalent, there having been 1,063 cases of gonorrhœa and 370 of syphilis treated among natives during the year. The further away a station is from the sea the more cases of syphilis are met with, Bornu having the greatest number in Northern Nigeria; scarcity of water and consequent lack of personal cleanliness probably explaining the fact in part.

Colonial Medical Reports.—No. 26.—Saint Lucia.

ANNUAL REPORTS ON THE HOSPITALS AND DISPENSARIES, 1904.

CASTRIES.

Alex. King, M.B., Ch.B., D.P.H., 2nd District Medical Officer for Castries.

In Castries better means of sewage collection and disposal should be adopted. The bucket system can hardly be dispensed with, but could easily be carried out on better lines, as it is capable of great improvement.

Bye-laws as to the disposal of domestic waste water should be enforced. The habit is to throw it on the ground in the most convenient place, thus producing a very foul state of the subsoil. This is especially objectionable as wells still exist, though apparently they are little used. The large prevalence of intestinal parasites is traceable to the same careless habit of throwing down filth around the houses.

There is a good deal of overcrowding both of persons in houses and of houses on the land. As things stand at present the space round each house is hopelessly deficient, resulting in the crowding together of outhouses which should be widely separate; for instance, privies are found next to and communicating with kitchens and servants' quarters, and cowhouses in the same relation to bakehouses.

It is an accepted fact that the death-rate varies directly with the density of the population, and though the Castries death-rate is wonderfully small it could be further reduced. At the same time this death-rate is not, I think, a very true index of the town's freedom from disease. In the present constitution of the population, owing to industrial conditions, there is an excess of young adults, and a population so constituted has naturally a small death-rate.

Although the town has a good supply of gravitation water, tanks still abound. They are very well as a stand by, but should be built so as to be easily inspected; should be covered so as to prevent access of mosquitoes, and should be cleansed at regular intervals. Until these provisions are carried out tanks should be looked on with suspicion, if not actually as a nuisance.

The rivers round the town are in general use for washing clothes and are not suitable for the purpose. The flow of water is small at best, and now the beds are fouled with soapsuds, &c. The woman who washes furthest upstream may get clean water; those below certainly do not. Disease might easily be spread in this way.

Anse-la-Raye village requires a better water supply. The plots round the houses are not well kept, and there are heaps of rubbish all through the village. The wash of the surf has piled up the sand till one of the beach privies has been left high and dry. The villagers continue to use it, so now there is a large collection of filth which is apparently never removed or even covered. The whole system of beach privies is objectionable, but when accidents of this kind happen it becomes injurious.

The ditch which runs parallel to the back of the village is stagnant, forming a splendid breeding-ground for mosquitoes. It also smells foul.

The village round Roseau Factory is dirty and badly kept.

Colonial Medical Reports.—No. 26.—Saint Lucia *(continued).*

ANSE-LA-RAYE DISPENSARY.

THE diseases treated at Anse-la-Raye Dispensary for the year 1904 were as follows:—

Intestinal Parasites	134
Malaria	57
Diseases of Digestive System	46
,, Respiratory ,,	24
,, Nervous ,,	7
,, Circulatory ,,	5

Senility	3
Indefinite	21
Returns	75
Total	554

The most remarkable feature is the total absence from the list of syphilis and gonorrhœa. Next is the extremely low percentage (3 per cent.) of tuberculosis. Following on the absence of venereal disease the percentage of cases of disease of male organs is very small.

Malaria increased enormously in the last two months of the year. The others are fairly evenly distributed.

DENNERY.

Edwin Wells, M.B.(Edin.).

At the end of July, Dr. Payne resigned charge of this district and I took over from him on August 1st.

The number of persons who consulted me in both Micoud and Dennery Dispensaries during the year was 1,470. Malarial fevers, worms and digestive disturbances claim the lion's share of attention.

Malarial fevers are prevalent in the autumn, though cases are seen here and there all the year round.

In August and September an epidemic of whooping-cough invaded the district, but was quickly got under control and stamped out.

The estimated population for the year 1904 was 4,500. There were 91 deaths during the year, giving a death-rate of 20·2 per 1,000. One hundred and sixty-seven births took place in the district, the rate being 37·1 per 1,000.

SANITATION.

The sanitary condition has been fairly good all round. No diseases could be traced directly to insanitary conditions.

The sanitary condition of Micoud has been very good, and it is one of the cleanest villages in the island.

I append a list of the diseases treated at the Dennery and Micoud Dispensaries and the annual return for the hospital.

List of diseases treated at Dennery Dispensary during 1904:—

SOUFRIÈRE.

J. A. Lestrade, M.B., C.M., District Medical Officer, Soufrière.

The health of the Second District was good. Beyond ordinary ailments there were very few noticeable diseases of a severe type among the people. I attribute this to the better scavenging now going on for some time, but principally to the new water supply given to the town. One sees very few cases now of those continued fevers and bowel complaints which raged formerly in the town during the hottest part of the summer and autumn season; though there were three mild epidemics of a contagious character during the year. Throughout the year, but principally about the time of the hot season, a skin disease, which was also prevalent the year before, was noticed. I believe this was caused by the irritation of minute particles of dust present in the atmosphere whenever the volcano of "Mont Pélée" at Martinique erupted, as it was first noticed after the first eruption in 1902.

About August, and for some time after, influenza was mildly prevalent, but it was practically of a harmless character.

At about the end of the year measles, with diarrhœa and bowel disturbances as an after symptom, began to show itself. It then spread in a southerly direction, and was still raging up to July last, when I gave over the district to Dr. Wells.

The institutions under my charge were well patronised. At the Soufrière Dispensary 1,224 people applied for treatment, of whom the greatest number were infants and children, brought for treatment for fevers caused by the irritation of teething and worms, and and often also of bad innutritious food.

At the Choiseul Dispensary the number of patients treated was 198, with 175 successful vaccinations.

At the Poor Asylum the number treated was 137; 94 were admitted during the year. The number of indigent and sick paupers must be increasing at the present moment in Saint Lucia by leaps and bounds.

The number of yaws patients treated during the year was 80. The appellation of "yaws patients" is patently a misnomer, as three cases of leprosy were sent to me from Castries for admittance, making a total, with those already in the asylum, of 7 cases treated during the year.

There were 11 deaths at the institution during the year; of these, 7 were due to yaws, 2 to debility and exhaustion consequent on tertiary syphilis, and 2 to leprosy.

At the Lunatic Asylum there were, at the beginning of 1904-4 female inmates; 7 were admitted, making a total of 11 treated during the year. One was discharged and 2 died. The cases treated were mostly epileptics and those suffering from senile dementia.

At the Soufrière Hospital 85 patients were treated, and of those 63 were admitted during the year: 65 were discharged cured or relieved, and there were 18 deaths.

VIEUX-FORT.

A. B. Duprey.

The last census seems to have been taken in the year 1901, the populations of Vieux-Fort and Laborie being then estimated respectively at 3,500 and 3,278 souls. The number of people in Laborie district for 1902 was estimated at 3,324, there being a small increase of 46. The Vieux-Fort and Laborie districts are very sparsely populated and consist of principally a labouring class of people mostly engaged in agriculture.

The births and deaths during the year 1904 as compared to those of 1903 are hereby represented in tabulated form :—

1903.

Districts	Births	Deaths	Birth-rate per 1,000	Death-rate per 1,000
Vieux-Fort	128	53	36·5	15·1
Laborie	142	58	43·3	17·6

1904.

Districts	Births	Deaths	Birth-rate per 1,000	Death-rate per 1,000
Vieux-Fort	117	45	83·1	12·8
Laborie	125	65	38	19·8

There were no serious epidemics during the year; a few cases of influenza occurred in January and February, but these were mild in nature. At the latter part of the year, viz., in August, a few cases of whooping-cough were treated in the dispensaries, but these soon disappeared. Malarial fever was prevalent but usually of a mild intermittent character, chiefly at the end of the year.

There appeared to be more deaths during the latter part of the year, say, between the months of August and November, than at the commencement of the year. Sudden deaths among children occurred fairly frequently, mostly due to untreated malaria contracted in the heights of the districts, and to a great extent also from infection by the *Ascaris lumbricoides*.

Throughout the year there was a want of rain felt in both districts. At Laborie there were more frequent showers than at Vieux-Fort. The highest records occurred during the months of June and August, when the rainfalls were 6·68 and 5·21 inches respectively; the total number of inches for the whole year being 45·27 inches, or 15·21 inches less than the preceding year. The commencement of 1905 was likewise characterised by a drought, the records being 1·69 for January, 1·64 for February, and up to date, March 20th, 1·10 inches. Between January and the middle of March, 1905, there was a constant piercing east wind blowing almost to a half gale; its effect upon the health curve of Vieux-Fort district was distinctly depressing. Bronchial affections and acute tonsillitis were then very frequent.

Malarial Fever.

There were a good many cases of fever treated as usual at both dispensaries, though far less in number than the preceding year. This may be owing to the drought which more or less characterised the greater part of the year, thus lessening the pools and drying up stagnant swamp water. Malaria is, however, latent in most people and only requires some slight depressing cause to bring out the whole phenomena of an attack of malarial fever. Of 1,031 persons seen at the Vieux-Fort Dispensary, 142, or 13·7 per cent., suffered from malaria, and in every case was benefited by quinine. There were two severe cases of fever treated in this hospital.

Dysentery.

This disease is present in sporadic form and in no particular season of the year. There were 14 cases during the year, scattered in different parts in both districts and these received special attention. I have no means of investigating microbic dysentery, but I would only like to suggest here a probable cause of dysentery, whether sporadic or epidemic. Dysentery, if I may be allowed to suggest, has a direct relation to the advance of agriculture in the West Indies. It is noticeably so in hilly countries, especially where large quantities of manure are being used for furthering the growth and keeping up the standard of West Indian products. The heavy rains are apt to wash down the rather loose manure into the streams and rivers, thereby constituting a source of danger to the population lower down who drink these waters. This disaster is to a great extent prevented in this district owing to the nature of the country, which is more or less level. Still, however, the danger exists, and the nature of the manure used, whether chemical or organic, makes little difference.

In the treatment of acute or chronic dysentery, I put great reliance on the use of sublimed sulphur, which in my hands invariably gives excellent results. The method of administering the drug has already been communicated in the Journal of Tropical Medicine in 1901. I have since found though, that the good results obtained do not depend upon the Dover's powder combined with it, but to the virtues of the sulphur alone.

Ankylostomiasis.

This so-called anæmia is widely prevalent in both districts, though cases do not often come to hospital for treatment. In one instance, that of a black man and a labourer, the anæmia was intense and the number of worms passed were few, yet he, however, recovered sufficient strength and colour to be discharged in a week. This man said on admission he could hardly get the necessary food to keep him standing. He improved rapidly on a liberal diet, and one could not doubt that his case was primarily one of starvation.

Lung Disease.

This cannot be said to be of very common occurrence. I have seen some cases of asthma, the treatment of which condition is very unsatisfactory, owing to the irregular attendance of these to the dispensaries.

Venereal.

Gonorrhœal affections are very common indeed and there are many who are crippled from gonorrhœal rheumatism. Ophthalmia and blindness from the same cause are frequent; I have seen 3 cases during the year of total blindness from this cause, one of whom died from pyæmia. Syphilis is exceedingly common and is on the increase. A goodly number are imported by labourers who have returned from Cayenne, but a great many get infected locally. The tertiary manifestations of syphilitic brain disease are sometimes seen; I saw two such cases last year.

Ascarides.

This affection is by far the most common in the districts. In fact, I do not remember any other place where the ascaris is more readily found. It is difficult to assume a cause for this extensive worm disease; sea-coast towns and villages are not more apt to be infested than inland towns and villages, but it is possible that the great quantity of pigs that are reared inside and around the towns may furnish a probable cause. Notter and Firth in, their "Theory and Practice of Hygiene," mention that pigs are infested by the same worm as are human beings and thus the disease is transmitted to man by contamination of "water from streams and ponds," or even the sands and loose earth where potatoes and other vegetables are grown. Not a few cases simulate acute meningitis.

Rheumatism.

I have already drawn attention to the frequency with which children and adults are affected with subacute rheumatism and heart disease. Considering how often it has been stated that acute or subacute rheumatism is not to be found in the Tropics, this should draw particular attention to the fact of its presence.

Yaws.

These were not many; only 5 cases attended the Vieux-Fort Dispensary; at Laborie also there were a few cases. It is a disease that affects the lowest classes and is to be found only in certain islands of the West Indies, and then only in certain localities. Yaws come from the heights of the districts.

The districts of Vieux-Fort and Laborie were fairly healthy during 1904. There is no special sanitary arrangement or water supply. The dry earth system prevails here.

The villages of Vieux-Fort and Laborie are full of small huts negligently built without any due regard to air space per head or to ventilation. A whole family are sometimes crowded in a small hut at night without even a window open to allow the admittance of fresh air, but on the contrary, all crevices are hermetically sealed either with cotton-wool or rags.

Table of diseases treated at Vieux-Fort Dispensary during the year 1904:—

Fevers	192
Worms	162

Numerical Returns.

During the year 1904 there were 1,262 cases admitted into hospital; in the previous year there were 1,639. Only those who urgently required attendance could be admitted, and this led to the exclusion of a large class of "No appreciable disease."

There were 82 deaths in a total of 1,343 cases treated, giving a death-rate of 6·1 per cent. There were 123 operations performed, of which a classification is appended.

The most important diseases treated are syphilis, malaria and intestinal parasites. Pulmonary tubercle is responsible for 16 deaths.

As a working basis it may safely be assumed that every adult labourer in Saint Lucia has had, or is actually suffering from, venereal disease.

(*a*) Soft chancres are not to my knowledge very prevalent; and unless they take on a phagedænic type are not seen by a medical officer, but are treated by the druggists or other bush vendors.

(*b*) Gonorrhœa seldom comes under observation unless complicated.

During the year 1904, 20 cases of stricture were treated in the Victoria Hospital.

Colonial Medical Reports.—No. 26.—Saint Lucia *(continued).*

It is exceedingly rare to come across a woman who has not some pathological condition of the generative organs, or in other words, one who has not been the victim of gonorrhœa, syphilis, or sexual psychopathy.

(*c*) Syphilis is very prevalent, and along with malaria and intestinal parasites constitutes the bulk of cases treated throughout the island.

In 1904 the total number of cases treated in the Victoria Hospital was 1,343; of these malaria accounted for 227, syphilis 321, intestinal parasites 156. This does not represent the true percentage, which is really much higher. Thus, on March 31st, of 68 patients in the hospital, indisputable evidence of syphilis was found in 33, and there were at least 10 others about whom no satisfactory conclusion could be formed.

In the study of West Indian syphilis it is of the greatest importance to realise the certainty and frequency of non-venereal syphilis; neither age nor moral standing is a barrier against contagion. The so-called varieties of "Yaws" are true manifestations of syphilis.

Among certain tribes in Africa early infection with syphilis is practised as a safeguard to the future health of the child, and in the West Indies the same belief prevails with regard to "Yaws."

Of late years it has been noticed that venereal syphilis has been on the increase in the town of Castries. Unfortunately, there are no available statistics. The facility with which work was obtained in the garrison town, which was also a coaling station, attracted large numbers of immigrants, many of whom were wanton vagrants from the neighbouring islands. Among this lot infection became very rife. In 1904 among males there were 20 cases of infection requiring operative interference, even to the extent of amputation of the penis.

The disregard of the populace to all sanitary and precautionary measures against diseases makes it a difficult problem to stamp out or even attempt a reduction in the parasitic affections.

Castries Dispensary.

During the year 1904, 7,102 cases were treated at the Castries dispensary, and 9,626 ulcers were dressed.

It appears needless to classify the ailments treated, as was done in former years under the various systems of the body. The type of cases treated presents no difference from the more correct classification afforded by the hospital returns. The prominent features in both are syphilis, malaria and intestinal parasites.

Colonial Medical Reports.—No. 27.—Basutoland.

MEDICAL REPORT FOR THE YEAR 1905.

By Dr. E. C. LONG.

Principal Medical Officer.

General Health.

The year 1905 was not so healthy as 1904. There were no epidemics of any magnitude or severity, but an increased number of minor ailments.

Speaking broadly, I should say that the general health of the Basuto is tending to a progressively lower standard, and the physical development to-day is inferior to that of the past generation.

This last point is illustrated by the low standard of the recruits seeking admission to the Bechuanaland Police. Of the last 50 candidates examined, all young men between the ages of 22 and 35, 20 per cent. were rejected on account of defective physique or bodily ailments.

I have, for some years now, noticed a decline in the physique of those who have attended school for several years, and I attribute it in part to the overcrowding and deficient ventilation in many of the school buildings.

The increase of tubercular disease in the country during recent years emphasises the danger of these defective buildings. There is a distinct danger that unless steps are taken to render school accommodation better, that the schools will become centres for the spread of tuberculosis.

The question of the cubic space and ventilation of school buildings in relation to the number of pupils is of great importance, more especially in those schools which receive boarders.

Something might be done by insisting on a limit to the number of pupils accommodated in any given building, making the Government grant contingent on this proviso being adopted, and insisting that plans of all school buildings should be first submitted to the Government architect.

At the vacation course for teachers, held at Maseru, in January, 1906, a few lectures on elementary hygiene were included in the course, and the teachers showed great intelligence in appreciating the lessons inculcated in these lectures. A year or so ago a small pamphlet on elementary hygiene was written and translated into Sesuto, but it should be included in one of the compulsory school readers.

Small-pox.

There were only two small outbreaks of this disease during the year. They were promptly stamped out by isolation and vaccination.

Fifteen thousand three hundred and eighty-five vaccinations were performed during the year, and the general condition of the people in this respect is satisfactory.

Enteric Fever.

Comparatively few cases have been recorded, and, as in other years, these were mostly imported cases.

Tuberculosis.

This is still increasing, 199 cases being recorded as against 155 in 1904. Tubercular glands in young people between the ages of 18 and 30 is the most common form.

Leprosy.

Only a few new cases have been noted.

Syphilis.

This disease shows no abatement. It is noteworthy that of some thousands of cases recorded during the year, in only six instances was the primary lesion observed.

The increased number of cases of congenital syphilis shows that a large number of people go untreated. The secondary manifestations are usually so mild that the people neglect them, and only come up for treatment for severe tertiary lesions.

Scurvy.

Very few cases came under notice, and those were all imported from the various labour centres.

Rheumatism.

All forms of rheumatism have been very prevalent. The acute cases are seldom seen, but judging by the large amount of valvular disease of the heart, they must be fairly common.

Lymphatic System.

A case of lymph scrotum was admitted into the Maseru Hospital in December, 1905. The blood was carefully examined for filariæ, but with negative results. He is a well-nourished young man, aged about 22, and the swelling was first noticed eight years ago, and has been gradually increasing in size. The tunica vaginalis contained an ounce of colourless serum.

This case is interesting, taken in connection with one of elephantoid swelling of the foot reported some years ago, in which filariæ were thought to have been observed in the blood. Specimens of the blood of this patient were forwarded to Sir P. Manson, who was, however, unable to confirm the presence of filariæ.

I have quite recently heard of a supposed case of elephantiasis of the leg in a native in Letsie's ward. My informant, who had spent some years in Central Africa, states that it is exactly like the cases he was accustomed to see there. I am endeavouring to get this patient under observation, and if successful a report with specimens of the blood will be forwarded for examination.

Urinary System.

An interesting fact has been elicited in connection with Bright's disease. It is that the patients are invariably chiefs or well-to-do natives who indulge largely in a meat diet. It is practically unknown amongst the common people.

Male Generative System.

A successful case of enucleation of the prostate was undertaken in the Maseru Hospital. The patient, aged 65, prior to the operation had two ounces of residual urine. Urine was passed by the normal channel fourteen days after the operation, and when the patient left the hospital there was no residual urine.

Diseases of the Eye.

Forty-five cases of cataract were operated on during the year. They were all of the senile variety, except one congenital cataract. The results were uniformly good, only one eye being lost from suppuration.

Glaucoma is still frequently met with, but only three cases were benefited by treatment. The remaining cases all came up for treatment after the glaucoma had been absolute for some years.

* At Richmond Hill Meteorological Station in the south of the island.

Colonial Medical Reports.—No. 29.—Cyprus.

MEDICAL REPORT FOR THE YEAR 1905.

By the CHIEF MEDICAL OFFICER.

PUBLIC HEALTH.

THE health of the island during the past year has, on the whole, been satisfactory, as, with the exception of an outbreak of measles, generally speaking of a mild type, which prevailed at the early part of the year almost throughout the whole of the island, and sporadic cases of typhoid fever, with conspicuously rare cases of diphtheria, no other infectious or contagious zymotic disease occurred during the year under report.

Malarial fevers, however, owing to the frequent late rains, were prevalent, particularly in the western portion of the island, where also the rains were more abundant. Unfortunately, the rural population, as a whole, place little importance on this disease, which is considered as a natural course of things, and not the slightest prophylactic precautions are taken to avoid it.

The opinions expressed by the different medical officers on the subject of the general health have been satisfactory, and I submit reports from the districts of Nicosia and Larnaca.

HOSPITALS AND OUT-DOOR DISPENSARIES.

In the six hospitals, 1,945 patients were treated, 118 deaths occurred, and 261 surgical operations were

performed. In the six district dispensaries 22,919 patients attended, whilst in the eight rural divisions 8,686 patients were visited by the rural medical officers during the year, the whole of these received medicines gratis.

Leper Farm.

The number of inmates in the farm on December 31st, 1904, was 109; there were 13 admissions during the year, 9 deaths occurred, whilst 112 remained on December 31st, 1905.

The general health was very satisfactory, as also that of the children of lepers who have been now for some time removed from the Leper Farm to a separate house in the town; they continue to be very healthy, without as yet showing the slightest sign of leprosy, and their elementary education is looked after by one of the attendants, who also acts as governess.

Lunatic Wards.

There were 19 admissions during the year to this institution, and 15 were discharged relieved or cured; 1 death occurred and 42 remained in the wards on December 31st, 1905.

The health of all the inmates was good, notwithstanding that many cases are brought in in a very debilitated condition, and the wards had more inmates than the accommodation should hygienically permit.

Quarantine.

Owing to the continuation of plague in Egypt, all arrivals thence were subjected to medical inspection and the disinfection of susceptible articles.

Three cases of small-pox were detected aud promptly dealt with at the quarantine ports; the disease did not enter the island.

Vaccination.

During the year 7,837 vaccinations were performed, of these, 7,420 were primary operations, whilst 417 were revaccinations.

Of these operations 6,739 were reported as being successful, 607 as unsuccessful, whilst 491 were not seen by the vaccinators a second time.

Animal Disease.

The veterinary surgeon's report, which I submit, deals fully with this subject.

Chemical Laboratory.

This branch of the department continues its most useful work with ever increasing satisfactory results.

NICOSIA.

Report by Dr. Robert A. Cleveland, District Medical Officer.

The general health of this district for this year has been fairly satisfactory. In the earlier months of the year there was an epidemic of measles which, I believe, was general throughout the island. No patients with this disease were admitted to hospital, and only 8 cases attended the out-patient department. There were many cases seen by me in private practice.

Colonial Medical Reports.—No. 29.—Cyprus—*(continued).*

THE epidemic was of a fairly mild type, and I saw no case of death from the disease.

There was no case of diphtheria during the year as far as the hospital statistics show, and I saw no case in private practice.

Typhoid fever is responsible for 3 deaths of patients treated in hospital, of which there were 8 cases. I have seen a good number of cases outside the hospital, and I believe the disease was fairly prevalent throughout the whole year. There was no case, however, amongst prisoners. I believe the Nicosia Town water supply to be pure till it reaches the aqueducts for distribution throughout the town, when it becomes liable to contamination. Some of the cases seen by me were no doubt traceable to the use of shallow well waters.

Malarial fevers seem to have been common in the towns and villages, chiefly in the hotter months, from June to October; cases, however, occur throughout the year. Where possible, a microscopical diagnosis is made, but it is impossible to deal with every case in this way, but all cases admitted to hospital are so diagnosed. In this connection an effort was made by me to institute a system of mosquito destruction during the spring and summer, and I was materially assisted by the Municipal Commission of the town of Nicosia. In one instance millions of Anopheles larvæ were discovered in the month of August in pools, caused by leakage from the town aqueduct. These were promptly destroyed, and the pools filled in, and the leak in the aqueduct stopped.

I am of opinion that the health of the towns and districts might be improved by the adoption of some system of mosquito prevention and destruction. In other parts of the world such efforts have been attended with success, as in the case of Havanna, Ismalia, and Port Smeltenham, and I believe the matter is worthy of the consideration of this Government.

NICOSIA GENERAL HOSPITAL.

This institution has been of service to the inhabitants of the town and district, and in not a few instances patients have travelled long distances, and even from other districts of the Island in order to get treatment. The number of beds is small and the figures remain much the same as last year. The hospital buildings are badly in need of repair and repainting, it being some years since this was thoroughly done, and I trust money will be available in the next financial year to carry out this very necessary work. I also beg again to draw attention to the absence of proper accommodation for the treatment of women, and also to the state of the floors of all parts of the building.

The dispensary and out-patients' departments are much in need of re-painting, but in other respects the buildings are in good repair.

In this department 6,359 dressings were applied, and the Nurse of the Colonial Nursing Association (Cyprus Branch) is employed in the out-patient department, when her services are not required outside the hospital. A total of 4,517 patients attended for more than one visit.

TABLE SHOWING TOTAL NUMBER OF IN- AND OUT-PATIENTS TREATED AT THE NICOSIA GENERAL HOSPITAL IN THE YEAR 1905.

	Civilian	Deaths	Police	Deaths	Total	Total Deaths

1903	6,769	20
1904	7,297	22
1905	6,937	29

Report by George A. Williamson, District Medical Officer.

GENERAL REMARKS.

As in former years, the diseases bulking largely are malarial fever, diseases of the digestive and respiratory systems, neuralgia, debility, diseases of the eye, of the cellular tissue, and of the skin.

SEASONAL PREVALENCE.

Purulent conjunctivitis, the seasonal prevalence of which may be given as from the middle of August to the middle of November, was not so frequently met with this summer as usual.

As might be expected, diseases of the respiratory system occurred chiefly during the late autumn, winter and spring.

Influenza appeared in epidemic form during the first quarter of the year, 100 out of the year's total of 117 cases being treated during these three months.

Fibricule was observed during the whole year, but was commoner during the first six months.

Dysentery, of which only 29 cases were treated during the year, occurred chiefly from April to August, 22 of the cases being treated during that period.

Rheumatism was seen chiefly during the early months of the year.

On the other diseases (except malarial fever, to which I refer in the next paragraph) season appeared to have no special influence.

MALARIAL FEVER.

The Malarial Incidence Chart for 1905, which I submit, is of the type I have formerly shown to be characteristic of the disease in Larnaca. The outstanding features are: (1) The presence of cases during January and February; (2) the almost entire

absence during March, April, May, and the first half of June; (3) the large increase in the number of cases in July, August, September, and October; (4) the considerable fall in November with a slight rise in December.

The heavy *late* spring rains of 1905 have had the result that such rains practically invariably have, of causing a severe malarial summer and autumn.

I have been much struck by the large proportion of cases of æstivo-autumnal fever and the very few cases of quartan fever this year. The former has greatly increased and the latter considerably diminished, while tertian fever retains more or less its usual proportion to the total number of cases of malarial fever, or is, perhaps, slightly less than ordinary.

I am quite unable to give any explanation of this distribution of the several types of malaria this year. All that can be said is that quartan fever is more typical of a cold malarial country, and æstivo-autumnal of a tropical malarial country, while it is probable that tertian fever occurs more commonly where there is a warm climate, with, however, a distinct difference in temperature between winter and summer.

During the year I have endeavoured to explain to the patients the method by which malarial fever is carried and the consequent rational means by which infection may be avoided. My object was to try to lessen the incidence, but I can truthfully say that the most intelligent remark made was simply "Just fancy!" and I am sure not one person followed the advice given.

Not only did my attempts at making the natives adopt preventive measures fail, but even in treatment they preferred to be guided by their own ignorance.

I fear that a people who will neither carry out the prophylactic measures explained to them, nor even take the trouble to come for the medicine which is supplied gratis to them, must continue to suffer: my sympathy lies with the poor children whose parents so neglect them, and whose lives are so frequently jeopardised by this criminal carelessness.

Would the people but use (such of them as possess nets) mosquito-nets and carry out the medical instructions as to treatment, the incidence and recurrence of malarial fever would both be remarkably diminished.

It has been asserted that malarial fever and cancer are not found together—an assertion with which my experience does not agree; but I may mention in this connection that only one case of cancer has come to my notice during the year. It is reported on elsewhere.

Bacteriological Work.

I have, since 1900, done a considerable amount of bacteriological work, having fitted up, at my own expense, a laboratory here. It has been very gratifying to find that such facilities to diagnosis as the bacteriological work gives has been appreciated by several of the medical practitioners. Thus, besides from medical men in Larnaca, I have received specimens for examination from Limassol, Polymedia, and Troödos.

The Public Health.

The public health in this district has been, apart from the large amount of malarial fever, good; no cases of diphtheria occurred during the year. Chicken-pox and measles occurred in Larnaca and in several villages, but most of the cases were mild. Enteric fever occurred less frequently than last year, and never reached epidemic form. Conjunctivitis was somewhat less than in 1904.

I have in former reports drawn attention to the absence of means by which the birth rate, marriage rate, and death rate can be calculated. These vital statistics are of very considerable value.

The District Hospital has been taken advantage of, as in former years, by large numbers of the sick poor, and is admitted to be a boon to the town and district.

Report by George J. Harvey, Veterinary Surgeon.

The animals inspected by me for exportation were: sheep, 6,894; lambs, 1,651; goats, 259; oxen, 1,253; pigs, 1,205; donkeys and mules inspected being 6 and 11 respectively.

Lambs were exported principally in March, April, May and June. Pigs all the year, bar June, July and August, and oxen all the year round.

There would have been far larger exportations but for quarantine having to be carried out in Egypt on Cyprus animals, when there were one or two local outbreaks of quarter-ill, anthrax and sheep-pox here. The law at present requires that the infected places, where only one or two animals die, should be gazetted and quarantined before legalised restrictions and penalties can be enforced, preventive measures taken, and the safe destruction of dead bodies enforced.

Thus, in one small place, such quarantine affects the export of the whole island.

A law as to the disposal of the body of any animal dying suddenly or within twenty-four hours from any unknown cause, by burial of the carcase whole, with lime if possible, and with penalties against the owner for not reporting or doing it, would save the villagers thousands of pounds a year.

The diseases prevalent during the past year have been quarter-ill, sheep- and goat-pox, and strangles, anthrax, generally distributed from Papho to the Carpas, and where the blacklegine vaccine has been used it has been most successful, and I have heard of no case of death after inoculation this year.

Sheep- and goat-pox have fortunately only appeared in an endemic form, and not generally, and been kept under control.

This I attribute to the instruction given by this office to the villagers in the method of preventive vaccination, which differs from their old method.

Strangles was very prevalent in the spring, and I attribute its spread to the movement of the Zaptiehs' horses. Whether it originated in the villages or towns I cannot say, but nearly all the Zaptiehs' horses were affected, and spread it. It may have been introduced by the imported Syrian horses.

Anthrax has only been reported in a few cases. The Government introduced some 500 double doses of vaccine, which was offered free to the native popu-

lation by advertisement, but only fifteen doses were used.

Report by W. Francis, Government Analyst and Lecturer in Chemistry.

I submit my report on the work done in the Government Analytical and Bacteriological Laboratory during 1905.

During the past year 239 samples were analysed, and 18 bacteriological examinations were made for the Government. One hundred and fifty-eight preparations of a chemical or bacteriological nature were made.

The number of private samples analysed was 23, and in connection with two of which I gave evidence in court.

One hundred and fifty-eight exhibits were received from the police for analyses and examination. For several years past cases of poisoning animals have been reported in the Limassol and Papho districts, but, thanks to the prompt action of the police in seizing all poisons from unauthorised persons, this serious practice has now ceased. At the request of the Chief Commandant of Police, I made, some years ago, a preparation for taking footprints in connection with criminal cases. The preparation was found to be satisfactory, except that in very warm weather it would not set quickly without the aid of cold water. I am now experimenting with a view of making a composition that will set in the warmest weather without the aid of a cooling agent. The new Food and Drugs Law came into force on January 1st, 1906.

The question of the purity of the water supplies has, as in previous years, occupied my attention. I have analysed forty-eight samples taken from wells in different parts of the Island. Samples of water taken from the source of supply are pure, but are often contaminated by bad earthenware pipes before consumption. For this reason I would suggest that filters be more universally used. Mr. J. A. Wanklyn, the famous water analyst, made many investigations concerning the removal of germs of disease and organic matter from water by filtration through silicated carbon. The result of all his experiments proved conclusively the great benefits that can be derived from the use of good filters. I would strongly suggest that filters be attached to all drinking fountains, and this would greatly improve the public health.

A considerable number of soils have been analysed during the year, both from manured and unmanured land.

The poorer soils are deficient in nitrogenous matter and phosphates.

Colonial Medical Reports.—No. 30.—Seychelles.

MEDICAL REPORT FOR THE YEAR 1905.

By Dr. J. E. ADDISON.

Acting Chief Medical Officer.

Vital Statistics.

The estimated population on December 31st, 1905, was 20·767, being an increase of 349 over the preceding year.

Annexure I. gives the number of persons who arrived at and left Seychelles, and the number of births and deaths during the year.

The birth-rate was 33·30 per thousand, and was lower than that of 1904, which was 34·92 per thousand.

The average birth-rate for the last seven years has been 31·94 per thousand.

The death-rate shows a satisfactory decrease, being 14·98 per thousand against 16·12 in 1904.

The average death-rate for the last seven years has been 17·21 per thousand.

The mortality among infants and young children was higher during this year, the number of children who died before reaching the age of five years was 126, being an increase of 31 on last year.

The number of juvenile deaths during the last seven years has been as follows:—1899, 121; 1900, 120; 1901, 148; 1902, 122; 1903, 155; 1904, 95; 1905, 126.

The principal causes of the mortality were to be found in intestinal complaints, chiefly due to worms and injudicious feeding, and to the epidemic of whooping-cough which was prevalent during the last two months of the year.

There were fifty-four still births and seven twin births during the year.

Meteorological Statistics.

Annexure II. shows that the year 1905 was warmer and drier than 1904. The mean temperature was 79·9, against 77·66 for 1904, which was the lowest temperature recorded.

Colonial Medical Reports.—No. 30.—Seychelles *(continued)*.

The total rainfall for the year was only 88·91 inches, against 107·05 inches for 1904. The rainfall was 18·14 inches less than last year.

The rainfall for the last seven years has been as follows:—1899, 88·41; 1900, 111·75; 1901, 102·26; 1902, 87·81; 1903, 132·96; 1904, 107·05; 1905, 88·91.

The average rainfall for the last seven years is 102·73 inches.

The south-east trade wind commenced to blow early in May, and continued until the end of November. It was not so strong and steady as is usually the case.

Prevalence of Sickness at Different Seasons.

The only epidemic disease which prevailed in the Island during the year was whooping cough, which commenced in the month of November, and continued till the end of the year, this disease not having visited the colony for very many years; the number of cases was large.

The type of the disease was severe, and it is interesting to note that in a precisely similar way to the measles, of which there was an epidemic some three years ago, the complications of the disease did not fall, as is usually the case, on the respiratory, but on the digestive system; a very large number of children were attacked, usually about the third or fourth week of their illness, by a form of enteritis, accompanied by the passage of blood and mucus in the stools, and, as might be expected, the children who harboured a number of worms suffered the most.

Nearly all the fatal cases were due to this complication.

As noted in the report of the Assistant Medical Officer, South Mahé, cases of tuberculosis of the lungs are on the increase; it would appear that the greater number of individuals attacked by this disease belong to the Indian creoles, who come from Mauritius, and I am of opinion that the increase in the number of cases is chiefly due to the fact that the number of this class coming to and residing in Mahé is greater every year, and of course each case that occurs forms a fresh focus of infection; and thus it is to be feared that a disease which a few years ago was quite uncommon will become of greater frequency.

As in the past malarial fever originating in this colony is unknown; the only cases seen are individuals who come to the Island from other countries already infected, these cases invariably do remarkably well.

Without doubt the immunity from this disease is due to the absence of the Anopheles mosquito.

Intestinal parasites form the greatest menace to young life, if neglected; the variety of parasite is almost invariably the *Ascaris lumbricoides*, it may be said that scarcely any of the juvenile population are free from this scourge, and the careful mother recognising this, always as a routine administers a vermifuge to her children two or three times a year; in many cases, however, where this precaution is neglected, the child gets his intestinal tract practically full of these parasites; which fact naturally interferes considerably with the proper nourishment of the child; cases are often seen when the parasites are present in sufficient quantity to give rise to elongated palpable tumours in the child's abdomen, and in several instances I have met with cases of subacute intestinal obstruction due simply to this cause. But, as mentioned when speaking of the whooping cough epidemic, the most danger is caused when the worms act as a complication, or perhaps the cause, of a form of enteritis, which seems to follow the exanthematous diseases.

Sanitary Condition of the Town of Victoria.

The scavenging and night soil service have been performed in a manner distinctly more satisfactory than in former years.

The water supply was abundant all through the year, but owing to the fact that the water is taken directly out of a reservoir without having time to settle and to no system of filtration being used, the water, after heavy rains, is very highly coloured, and contains a very large amount of vegetable matter, which is washed into the rivers by the rains.

Report by J. E. Addison, Acting Chief Medical Officer.

Reports of the Assistant Medical Officers of South Mahé and Praslin districts are submitted herewith. Both reports point out the great improvement in the general health of their districts.

The death-rate of 11·06 for South Mahé is very low, being a decrease of 2·95 per thousand as compared with 1904.

Praslin has a death-rate of 13·77 per thousand, being less than the preceding year, which was 14·08 per thousand.

Vaccination.

Vaccination this year has given good results, viz.:—

	Victoria	South Mahé
Successful 1st time ...	332	138
,, 2nd ,, ...	70	17
,, 3rd ,, ...	13	—
Unsuccessful	28	—
	443	155

In August, 1905, compulsory re-vaccination was performed in the town of Victoria, as small-pox was very prevalent in the ports with which Mahé is in communication. Happily, the inhabitants of Seychelles have escaped infection.

Quarantine Services.

The quarantine station at Long Island was used during the earlier part of the year.

The station has a steam disinfector, which is always kept in good condition and ready for use at any moment.

The guardian continues to keep the property under his charge in a very satisfactory condition.

Hospitals and Dispensaries.

Annexure III. gives the monthly return of out-patients treated at the public dispensaries and number

of cases treated at the Victoria Hospital during the year 1905.

The number of patients treated at the public dispensaries has been higher than usual, this being entirely due to the prevailing poverty amongst the populace.

This institution received 332 patients for treatment during the year 1905, viz: 258 males and 74 females.

The number of deaths in hospital was 14; being 6 less than during 1904, and giving a death-rate of 42 per cent.

Annexure IV. gives the cases treated at the Victoria Hospital, and cause of death.

Dr. Robert Denman, the Chief Medical Officer, left the Colony on April 9th, 1905, on leave of absence, meanwhile Dr. Ande Gruchy acted as Chief Medical Officer.

Report of First and Second Divisions South Mahé. By John Thos. Bradley, Assistant Medical Officer, Anse Royale.

PART I.

The health of the district continued good until the end of November. At the end of that month whooping-cough entered the district, although no deaths from this disease occurred up to the end of the year, yet I am of opinion that as the disease progresses its virulence will increase, and it will result in the weeding out of weak and debilitated children.

In former reports I drew attention to the fact that tubercular disease was not to be found in South Mahé. It is with regret that I note for the past two years that this cruel disease is making progress. Slowly but surely the insidious approach can be observed, and in future years tuberculosis will have to be reckoned as one of the diseases that active and prompt steps will have to be taken against.

Phthisis is at present occupying world-wide attention; scientific societies all over the world occupy themselves with its causation and treatment. At times it is suddenly reported that a remedy to combat the disease has been discovered, and after a more or less extensive trial the remedy is abandoned, and so year after year we get reports of wonderful remedies, and after a time it is found that the new remedies are no improvement on the old. When a disease is complimented by having so much attention paid to it there is no doubt that its ravages and the death-roll caused by it must be considerable, and I consider that tubercular disease, under all its different forms and manifestations, is one of the greatest scourges of the human race. Taken as a fact that the disease has invaded Seychelles, the people should be educated up to the disease; they should have explained to them what science has done and is doing to stay and arrest its progress, and unless a correct view is brought home to the people the arrest of such an insidious disease is almost impossible.

Return of Diseases and Deaths of Europeans in 1905 throughout the Seychelles.

GENERAL DISEASES.

Colonial Medical Reports.—No. 30.—Seychelles (*continued*).

FIFTY years ago the treatment was one of hot and confined rooms, all sources of air being carefully excluded, and the patient was kept like a hot-house plant. To-day the pendulum has gone to the opposite extreme: Fresh air and plenty of it, is the cry, and instead of keeping patients confined to close and stuffy chambers, their treatment is what is called the out-door and sanatorium. This wonderful change in treatment is sanctioned not only on scientific grounds, but on the splendid results now being published of the diminution in the death-rate where open-air treatment is carried out, and these results compared with those obtained under the old *régime*.

The question now at issue is, Can an open-air treatment be carried out with successful results at Seychelles? There are a great many people at Seychelles—in fact, the bulk of the population—who, for lack of means, are unable to take a voyage to South Africa, Algeria, or any of the usual health resorts which are laid down as suitable for individuals suffering from consumption. Under these circumstances the disease has to be combated at home, and I am of opinion that success in the treatment of phthisis can be obtained here, if the disease is taken in time and before it has obtained too firm a grip on the individual.

The question is, what is an ideal climate for tuberculous patients, and how can Seychelles be looked at from this point of view. I hold that the question of climate is less significant than that of *régime*, and it is to the advantage of the great majority of patients to be treated under the normal climatic condition of the individual.

An ideal climate for tuberculous patients is one having a pure and dry air which is frequently in mild movement, a maximum of sunlight, relatively equable temperature and warmth, freedom from dust, a certain amount of shelter, combined with a picturesque landscape and extreme stillness; this would be an ideal climate, in my opinion, but I do not know any country that fills exactly the conditions.

Varieties of climate for tubercular patients may be grouped thus:—

(1) Sea-coast climates.

(2) Desert climates.

(3) Forest and woodland climates of relatively small elevation (say 150 to 1,500 feet).

(4) Mountain climates (say 1,500 to 10,000 feet or more).

Seychelles is a sea-coast climate, is has the advantages of a pure air, no extreme ranges of temperature; it has the disadvantage of being too humid, and is often relaxing and enervating. I would not recommend an individual to seek Seychelles as a health resort, but I am strongly of opinion that cases of phthisis can be combated with here, as well as in a good many parts of Great Britain and Ireland The French and Italian Riviera, Madeira, &c., are all sea-coast climates, and are all used as health resorts for consumptive individuals; in late years I understand that the Madeira Islands are not so much used, owing to the depressing and weakening influence on consumptive people. Yet the great question is to cure the patient, and to undertake the cure (other things being equal) under the conditions which he must meet when recovery has taken place, and this is the issue that has to be faced by the inhabitants of Seychelles.

To sum up, the modern treatment of the disease should be combated in Seychelles on the following lines:—

(1) Improve the resistance of the individual to the disease.

(2) Take measures to attack, or at least neutralise, the products resulting from the growth and development of the tubercle bacillus within the body.

(3) Relieve the more important symptoms and complaints.

(4) Prevent the progress and advance of the disease in the community.

The improvement under (1) can be carried out on the lines that are followed by the principal sanatoria of the world, viz., fresh air and sunlight, rest, graduated and progressive exercise, dietary, skin hygiene, and medication; (2) and (3) are in the domain of the physician, who should take advantage of the latest discoveries; (4), which is probably the most important, should be met with by educating the public to the disease, by a system of segregation, and the establishment of a sanatorium in which all patients who were attacked by the disease would be compelled to reside.

Referring to pneumonia: during the year five deaths occurred; the mortality rate of this disease increases as you approach the Tropics, and from an examination of statistics of different countries I find that this is borne out.

There is an epidemic of whooping cough amongst the children, and I find that vaccination not only modifies the course of the disease, but in some cases is curative in its effects. I find that children, after vaccination, get a very mild form of the disease, that the spasms are absent, and the vomiting and other disagreeable symptoms do not make their appearance.

The mortality of children under one year is 16; a good number of the children only survive birth an hour or so, and some die within the first week of birth; all the same, more than one-fourth of the deaths that occur can be placed under the first year of life.

PART II.

VITAL STATISTICS.

As in former years, further on I have attached tables, showing a comparison of the births, deaths, and still-births of the years 1902 to 1905, also comparative tables of the ages at which death occurred during these years.

In my report of last year I tried to show what is the danger zone, &c., in the life of the inhabitants of Seychelles, and also the period more favourable to life. The most favourable period is probably between the ages of 30 and 45, and the dangerous zones the first year of life and after 55.

There is practically no increase in the mortality of children under 5 years, but in the year 1906 I am afraid the epidemic of whooping cough will have a marked increase on the death-rate under 5 years. In 1902 the number of deaths of children under 5 years

was 28, in 1903 it was 21, in 1904 it was 17, and in 1905 it was 20; so that practically for three years the death-rate has not changed.

Taking the births as 166 for the year 1905 and the deaths as 51, the increase in population for the year 1905 is 115; this increase, added to the increases of 1902, 1903, and 1904, makes a net increase of 408 for these four years.

1901	(Census taken in that year), population...	4,203
1902	Estimated population to December 31st	4,301
1903	,, ,, ,, ,,	4,404
1904	,, ,, ,, ,,	4,496
1905	,, ,, ,, ,,	4,611

The number of deaths for the year in South Mahé was 51, a diminution of 12 as compared with the year 1904. I think this is below the average; anyway, it is a small average for the year. As usual, a good number of old people died during the year. There were 7 deaths over 50 and under 60 years; 10 under 80 years; 1 under 90 years, and 1 over 90 years.

Taking the estimated population as 4,611, this works out a death-rate of 11·06 per thousand, being a diminution of 2·95 per thousand as compared with 1904.

The principal diseases that caused death during 1905 as as follows: Senile decay, 10; gastritis, 8; pneumonia, 5; hemiplegia, 2; endocarditis, 2; aneurism of aorta, 2; Bright's disease, 2.

During the year 1905 there were only 4 still-births, for the past three years the number was 11 each year.

During the year 1905 there were 166 births, an increase of 11 as compared with 1904.

The average birth-rate per thousand for 1905 is 36·00, being an increase of 1·53 per thousand as compared with the preceding year.

Part III.

Dispensaries of Anse Royale and Anse Boileau.

The dispensary of Anse Royale was well attended during the year on Mondays, Wednesdays, and Fridays, by the poor. During the year there were 504 consultations, being an increase on the year 1904 of 104 patients.

The dispensary was held at Anse Boileau every Thursday morning. The number of consultations for the year was 104.

As in former years, I have attached tables showing the diseases treated at the dispensaries and the number of consultations under each disease.

Vaccination.

The vaccine lymph supplied was excellent, and reflects credit on the preparation and maker; even after five and six weeks it still had its vitality. There was a small-pox scare during the year, and an extra supply of vaccine was supplied, some of it came from Madagascar, and the quality from this source was not good—after two weeks it was useless; the extra supply that came afterwards was excellent.

During the year I vaccinated all Government employees in South Mahé, including the cantoneers; the bulk of the school children attending at Anse Royale were also vaccinated. Of the general public, about 300 adults came to me for the free vaccination. In almost all cases the vaccination was successful, but some of the adults got marked swelling of the arms and glands in the axilla, accompanied by a severe reaction.

During the year I vaccinated 155 children; all the cases were successful; 138 at the first attempt, 17 at the second.

Part IV.

Surgeon's Work in Police Cases.

During the year there were 32 police cases at Anse Royale of wounds and blows, and 1 at Anse Boileau. Most of the cases were of a trivial nature, none of them were dangerous to life.

Accompanied by the police I examined and enquired into two deaths in my district, and one just outside the limits of the ninth mile at Anse Boileau. The first of these cases occurred on January 22nd, 1905. Accompanied by Sub-Inspector Tonnet, I went to Grand Police, and after examination of the body I found that death was due to drowning; evidence brought forward showed that it was accidental. The next case occurred on December 25th, 1905, at Anse Boileau; the man in this case had committed suicide in his bath-room. The case outside my district was that of an old man, aged about 80, who, one Sunday afternoon, cut short his life by hanging himself in his bedroom. Hanging is the method preferred by the natives when they wish to commit suicide.

Comparative Table of Births, Deaths and Still-births during the Years 1902, 1903, 1904 and 1905.

Years	Births	Deaths	Still-births	Remarks
1902	157	59	11	Births in 1903 exceeded that of 1902 by 12; there is a dimunition of 14 in the year 1904 compared with 1903; in 1905 the births exceed those of 1904 by 11.
1903	169	66	11	
1904	155	63	11	The year 1905 is the lowest death-rate in South Mahé for the past four years. The still-births have fallen in 1905 to 4.
1905	166	51	4	

Births, Deaths, Still-births and Marriages, 1902 to 1905.

Years	Births per 1,000	Deaths per 1,000	Still-births per 1,000	Marriages per 1,000	Remarks

PRASLIN DISTRICT.

Medical Report for the Year 1905. *By Dr. R. Laidlaw, A.M.O.*

THE inhabitants of the Praslin District have again enjoyed, during 1905, a twelvemonth of comparative freedom from sickness and disease, accompanied, as is usual, by a low death-rate and a high birth-rate.

Some particular features of the health of the district and its medical institutions require special notice.

ROUND ISLAND ASYLUM.

In the Leper Home and Pauper Camp, located on Round Island, the population at the beginning of the year was composed of 9 lepers and 10 paupers, and at the end of the year it was composed of 11 lepers and 15 paupers. That is, the diminished income of the labouring class, through lessened employment, has caused an increased demand for Government help in the case of the incapable and the infirm. Throughout the year all the inmates have shown a spirit of contentment and gratitude. Although their daily life is limited and monotonous in its interests, they have not been unhappy, or only when disease was acute. Basket-making, poultry-keeping, and rock-fishing are pursued by several in a fitful fashion, and they are the most cheerful of all. The majority prefer to sit idle in the sun, and do nothing but talk and smoke, and so proclaim practically their belief that idleness is happiness!

DISTRICT DISPENSARIES.

The two dispensaries at St. Anne and Grand Ance, Praslin, and the third at Ladigue have continued free medical help to the more destitute sick. This help, as formerly, has been much appreciated, and now and then, where benefit received was marked, has been very warmly acknowledged.

The number treated during the year has been: 323 new and 212 old cases, as against 243 new and 165 old the year before.

In an appendix the more frequently occurring ailments are enumerated. Of these, the debilitating diseases dependent on or associated with anæmia are the most important, and the most difficult to remedy. More than one generation, in not a few cases, have clearly contributed to the cachectic state and its concomitants. So, prolonged dietetic treatment is indicated as much as ordinary medical treatment.

PARASITIC DISEASES.

The chief parasitic disease is the round-worm, and few young people, if any, are exempt from its attack. Recently, one vermifuge dose administered to a child of six caused the evacuation of above 100 worms! The more formidable tape-worm is rare. We met with one case only in the course of the year.

Tineas of the scalp and skin are not uncommon; they are chiefly found in the case of those who notoriously neglect personal cleanliness. A widespread notion prevails, even amongst the better educated, that a scalp eruption should not be washed. Hence the unsightly heads of many otherwise healthy children.

EPIDEMIC DISEASE.

The district has throughout the year been entirely exempt from epidemic forms of trouble, except influenza colds and sporadic chicken-pox, and the last has been limited in extent, and not dangerous in type.

LEPROSY.

Leprosy is not increasing. An enquiry has been made regarding the possibility of procuring and using in Seychelles the specific remedy associated with the name of Captain Rost, of the I.M.S., which he had termed "leprolin." The announcements of its efficacy, however, seem to have been premature, and it is not as yet available. There is no doubt, however, but that a serum remedy of that special type will ere long be in effective use.

Colonial Medical Reports.—No. 30.—Seychelles (*continued*).

Wounds and Fractures.

The accidents arising from edged tools still abound, while dislocation and fracture occur occasionally. The gross neglect of surgical instructions, and the attempts to try if something else will not hasten the cure, make one desire a local hospital on a small scale, to control and maintain, for the necessary time, the surgical appliances.

Vaccination Results.

The vaccine lymph has given good results on the whole, as far as concerns that received from England. The lymph received from Madagascar, in the sudden precautionary measures against a possible invasion of small-pox, did not seem in the district to give results as favourably.

Birth and Death-rates.

The considerable number of 119 births were registered during the year. A large proportion of these are children born out of wedlock. Of the 119 the legitimate were 72 in number, and the illegitimate 47.

Forty-two deaths were registered throughout the year, and of these ten were the deaths of infants under one year, occurring very much, it is to be feared, from maternal ignorance or lack of sufficient care.

The estimated population of the district on January 1st, 1905, was 3,049, and the deaths being 42, gives a death-rate of 13·77 per thousand of the population. The year immediately preceding this figure was slightly higher, viz., 14·08.

APPENDIX.

The more Common Dispensary Diseases.

Abscess.
Amenorrhœa.
Amputation.
Anal fissure.
Anæmia.
Anorexia.
Antrum abscess.
Asthma.
Ascites.
Blenorrhagia.
Bronchitis.
Bubo.
Cardiac palpitation.
Cardiac valvular disease.
Cataract.
Cephalalgia.
Cerebritis.
Colic.

MEDICAL REPORT FOR THE YEAR 1905.

By J. E. GODFREY.

Surgeon-General.

RETURN OF THE STATISTICS OF POPULATION FOR THE YEAR 1905.

	Europeans and Whites	Africans	East Indians	Chinese	Mixed	Native Blacks	Aborigines	Total
Number of Inhabitants in 1904 ..	15,698	1,718	125,896	2,533	33,833	115,444	6,801	301,923
,, Births during the year 1905	377	..	4,093	75	1,202	4,069	378	10,194
,, Deaths ,, ,, ,,	453	109	3,239	89	679	3,391	354	8,314
,, Immigrants ,, ,,	..	..	2,218	131	..	..	..	2,349
,, Emigrants ,, ,,	..	..	2,561	201	..	..	..	2,762
Number of Inhabitants in 1905 ..	15,622	1,609	126,407	2,449	34,356	116,122	6,825	303,390
Increase	..	..	511	..	523	678	24	1,464
Decrease	76	109	..	84	..	..	..	..

POPULATION.

Estimated population (1905), 303,390; births (1905), 10,194; deaths (1905), 8,314; birth-rate per 1,000 (1905), 33·6, (1904) 30·3; death-rate per 1,000 (1905), 27·4, (1904) 28·8.

MORTALITIES.

The relative mortalities in the different quarters were: March quarter, 2,172; June quarter, 1,808; September quarter, 2,161; December quarter, 2,173.

MALARIAL FEVERS.

These showed the highest number of deaths, and were again highest in the September quarter, the June quarter also again showed the lowest number, and the December quarter the next highest number of deaths.

DIARRHŒAL DISEASES.

These showed the next highest number of deaths, the March quarter being responsible for the largest number of cases and the December quarter for the smallest. The June quarter was lower than the September.

BRONCHITIS AND PNEUMONIA.

These diseases were again principally confined to the East Indian race. The totals for the third and last quarters were about the same, and were higher than the first and second quarters, which were about equal.

PHTHISIS AND OTHER FORMS OF TUBERCULOSIS.

These were highest in the December quarter, but there was very little difference between that quarter and the first. The second and third quarters were about the same.

KIDNEY DISEASES.

The deaths from these diseases were highest in the December quarter, the March and September quarters were about the same and were higher than the June quarter.

There were a few sporadic cases of beri-beri, typhoid or enteric and blackwater fevers, but I am again glad to report that the deaths from these diseases were very few.

None of these diseases appeared in an epidemic form.

RETURN OF DISEASES AND DEATHS IN 1905 AT THE FOLLOWING INSTITUTIONS:—

Georgetown Hospital, Berbice Hospital, Suddie Hospitals, Bartica Hospital, Morawhanna Hospitals, including Arakaka Ward.
